§ 23. The Higher Manganese Sulphates—Manganic Alums

According to L. Carius,[1] manganosic oxide dissolves in cold, conc. sulphuric acid, or in an acid diluted with twice its weight of water, forming a columbine-red soln. which becomes carmine-red when diluted with water. If one part of pyrolusite

is heated with 13 parts of conc. sulphuric acid until half the available oxygen is evolved, and the mass then projected into cold water, a bright red soln. is obtained. R. Phillips found that native manganic hydroxide does not dissolve in sulphuric acid under these conditions, and L. Carius obtained a similar result with dil. sulphuric acid and artificial manganic hydroxide free from manganous hydroxide ; but curiously enough, if manganous hydroxide is also present dissolution occurs, and a deep red soln. thought to contain **manganosic sulphate**, $Mn_3(SO_4)_4$, is formed. If conc. sulphuric acid acts on manganic hydroxide, manganic sulphate is formed. The red soln. of manganosic sulphate precipitates hydrated manganese dioxide when heated, and, without evolving oxygen, manganous sulphate is formed. C. Fromherz observed that reducing agents—sulphur dioxide, nitrous acid, stannous chloride, ferrous sulphate, and mercurous nitrate—decolorize the liquid and form manganous sulphate. Acetic acid, alcohol, naphtha, turpentine, lavender oil, and starch act similarly ; oxalic acid, gum, tartaric acid, and hydrochloric acid and water turn the liquid brown before decolorization ; and arsenic trioxide gives a brown precipitate. C. F. Schönbein observed the red soln. is decolorized by hydrogen dioxide.

C. F. Böhringer, W. Lang, H. Merzbach and J. F. Smith, and K. Puls considered the sulphates of ter- and quadrivalent manganese to be formed as intermediate stages in the reduction of potassium permanganate dissolved in conc. sulphuric acid. L. Carius prepared **manganic sulphate**, $Mn_2(SO_4)_3$, by triturating natural or, better, artificial manganese dioxide with conc. sulphuric acid, and heating the mush gradually to 138°. The evolution of oxygen ceases at 110°, and the mass is then greyish-violet ; at 115° to 118° it darkens in colour ; and at 138° it becomes dark green. The mixture is poured on a porous tile to remove the sulphuric acid, and the residue is rubbed in a mortar with warm, conc. nitric acid —free from nitrous acid. The acid is then removed by spreading the mixture on a porous tile, and the treatment repeated half a dozen times. The product is warmed in a porcelain basin on an oil-bath at 130° until vapours are no-longer given off, and then preserved in dry, sealed tubes. Manganic hydroxide free from manganous oxide can be heated with conc. sulphuric acid at 100°, and then similarly treated. According to B. Franke, manganic sulphate can be prepared by warming a mixture of 8 grms. potassium permanganate and 100 c.c. of sulphuric acid, when some oxygen is given off, and an acid sulphate is formed. If heated to a higher temp., the mixture becomes green. The excess of sulphuric acid is removed by suction on a porous tile, and by heating the product on a sand-bath. K. Elbs, and F. Goerbig obtained the solid by the electrolysis of a soln. of manganous sulphate in $8M\text{-}H_2SO_4$ with platinum electrodes.

Manganic sulphate is a dark green, amorphous powder which can be heated to 160° without decomposition, but at a higher temp. it is decomposed into sulphuric acid, oxygen, and manganous sulphate. G. Beck gave 3·24 for the sp. gr., 122·8 for the mol. vol., and 85 Cals. for the heat of formation from the oxides. A. Chilesotti measured the e.m.f. of cells of the types : $Pt \mid Soln.Mn^{III} + Mn^{II} \mid 2N\text{-}H_2SO_4$, $Hg_2SO_4 \mid Hg$, and $Pt \mid Soln.Mn^{IV} + Mn^{III} \mid 2N\text{-}H_2SO_4, Hg_2SO_4 \mid Hg$, and calculated the normal potential $Mn^{\cdots} \rightarrow Mn^{\cdots} = 1.55$ volts ; and the normal potential for $Mn^{\cdots\cdots} \rightarrow Mn^{\cdots} = 1.65$ volts. These high values explain the powerful oxidizing action of electrolytically oxidized soln. of manganous sulphate. For G. Grube and K. Huberich's observations on the oxidation potential, and the hydrolysis, *vide supra*, manganous sulphate. R. H. Weber said that the atomic magnetism of manganic sulphate is less than 0·0115. According to L. Carius, the salt is very hygroscopic, and small quantities of the salt deliquesce in a few seconds in air to form a clear, violet soln. which soon becomes brown and turbid owing to the separation of hydrated manganese oxide. With a large proportion of water, a brownish-black mass is formed ; and with a small proportion of water, heat is developed, the mixture becomes reddish-brown, and then forms hydrated manganese oxide and sulphuric acid. B. Franke added that with water, the salt decomposes into

sulphuric acid, manganous sulphate, and a mixture of manganous oxide and manganic acid; dil. sulphuric acid forms the acid salt indicated below; and L. Carius added that dil. acids act like water. With conc. sulphuric acid and a little water, the salt forms a reddish-brown basic salt, without much passing into soln.; with conc. sulphuric acid, the green salt can be heated up to nearly the b.p. of the acid without decomposition, and, with the boiling acid, it gradually dissolves as manganous sulphate with the evolution of oxygen. Traces only of manganic sulphate dissolve in cold, conc. sulphuric acid to form a bluish-violet soln., and with the hot acid a violet soln. is formed. A. Schumrick found that a litre of $7M$-, $8M$-, $10M$-, $12M$-H_2SO_4 dissolves respectively 8·63, 1·74, 0·26, and 0·26 grms. of manganic sulphate. On standing, the amount 8·63 grms. in soln. is reduced to 7·20 grms. by hydrolysis and precipitation. In the presence of an excess of potassium sulphate, 0·64 grm. is dissolved. Manganic sulphate does not dissolve in cold, conc. nitric acid, but at 100° it becomes brown; it forms a brown soln. with conc. hydrochloric acid, and chlorine is given off. It behaves towards organic substances like a mixture of manganic oxide and sulphuric acid; the action is faster if the temp. be raised. K. F. Ochs measured the electrode potential of soln. of manganic sulphate in sulphuric acid.

B. Franke found that if 8 grms. of potassium permanganate and 100 c.c. of conc. sulphuric acid are warmed up to about 70°, not over 100°, some oxygen is evolved, and on cooling **manganic dihydrotetrasulphate**, $Mn_2(SO_4)_3.H_2SO_4.4H_2O$, separates out. The sulphuric acid is poured off, and the product washed with alcohol, and ether. The dark reddish-brown crystals lose sulphuric acid and water when heated, and form green manganic sulphate. If treated with a little water, equimolar parts of manganous sulphate, hydrated manganese dioxide, and sulphuric acid are formed. Hence, B. Franke represented the constitution of the salt by $Mn^{II}=(SO_4)_2=Mn^{IV}SO_4.H_2SO_4.4H_2O$. When treated with dil. sodium carbonate, brown manganic oxide is formed. Soln. of manganic sulphate in sulphuric acid were prepared electrolytically by E. Frei, and A. Chilesotti. A 4 per cent. soln. of manganous sulphate in sulphuric acid, of sp. gr. 1·453, was electrolyzed at 60° with a platinum anode and a current density of 4 amp. per sq. dm. The anodic liquid was contained in a porous pot. After some days, a large part of the salt separated out in tabular crystals.

C. Lepierre prepared **ammonium manganic tetrasulphate**, $(NH_4)_2SO_4.Mn_2(SO_4)_3$, or *anhydrous manganic alum*, by adding a mixture of equal vols. of nitric and sulphuric acids to ammonium manganous trisulphate, in the presence of an excess of ammonium sulphate. The crystals can be purified by successive treatment with hot, conc. sulphuric acid, glacial acetic acid, and dry ether. W. Lang prepared this salt by electrolyzing in an anode cell, lined with lead, a soln. of ammonium manganous sulphate, by a current density of 3·5 amp. per sq. cm. C. Lepierre found that the violet-brown, hexagonal crystals have a sp. gr. of 2·40 at 11°; they are decomposed by water, forming manganic oxide; they are insoluble in ether, benzene, and conc. sulphuric acid, but they dissolve in a mixture of equal vols. of sulphuric acid and water. When heated alone or in the mother-liquor, the salt decomposes with the evolution of sulphur dioxide and oxygen, and a soln. of ammonium manganous sulphate is formed. According to E. Mitscherlich, if pyrolusite be heated with conc. sulphuric acid, and the red soln. be treated with ammonium sulphate, the liquid furnishes dark red, octahedral crystals of what were regarded as the *tetracosihydrate*, or *ammonium manganic alum*, $(NH_4)_2SO_4.Mn_2(SO_4)_3.24H_2O$, that is, $NH_4Mn(SO_4)_2.12H_2O$; but O. T. Christensen showed that something is wrong with the inference, for the products contained not $24H_2O$ but rather 8 to $10H_2O$. Indeed, in order to prepare the manganic alum with $24H_2O$, it is necessary to work at a low temp., say —25° to —30°, for the salt is unstable at ordinary temp. and melts in its water of crystallization. The alum is obtained by dissolving 1·32 grms. of ammonium sulphate in 30 c.c. of dil. sulphuric acid (1 : 3), and mixing slowly, with stirring, with 5·36 grms. of powdered manganic acetate. The soln. is

cooled in a platinum dish by means of a mixture of solid carbon dioxide and ether. The coral-red, crystalline precipitate cannot be filtered from the mother-liquor at ordinary temp., and the cold mush of crystals and mother-liquor is poured on a porous tile previously cooled by the same freezing mixture, and kept in a cooled vessel for an hour. The crystals of the ammonium manganic alum at ordinary temp. melt in a few minutes to a liquid which is almost black in colour. The salt is decomposed by water, like manganic salts in general.

According to R. J. Meyer and H. Best, if sulphuric acid be added to a soln. of potassium permanganate in acetic acid, keeping the liquid cool, **potassium manganic tetrasulphate**, $K_2SO_4.Mn_2(SO_4)_3$, or *potassium manganic alum*, is quantitatively precipitated. The crystals are washed with acetic acid, and dried over sulphuric acid, and potassium hydroxide. B. Franke obtained the same salt by adding water and potassium permanganate to the green mother-liquor obtained in the preparation of manganic dihydrotetrasulphate (*q.v.*) and warming the mixture, when oxygen is given off and reddish-brown crystals are deposited. These are separated from the mother-liquor on a porous tile ; washed with alcohol, and ether ; and dried by warming them. R. J. Meyer and H. Best found that the salt dissolves in conc. sulphuric acid, forming a violet soln. ; in moderately conc. acid, forming a red soln. ; and in dil. sulphuric acid, forming a brown soln. from which colloidal manganic hydroxide deposits. E. Pietsch and co-workers discussed the efflorescence of crystals of manganese-alum. When the salt is heated, B. Franke observed that it decomposes into manganous sulphate, sulphur trioxide, and oxygen. It is deliquescent in moist air, forming a red soln. ; and it is decomposed by water into sulphuric acid and a 1 : 1 mixture of manganous sulphate and manganic acid. E. Mitscherlich's preparation of the manganic alum is wrong, because O. T. Christensen was able to prepare the *tetracosihydrate*, $K_2SO_4.Mn_2(SO_4)_3.24H_2O$, or $KMn(SO_4)_2.12H_2O$, as in the case of ammonium manganic alum, from soln. cooled to a low temp. F. G. Berend described the attack of crystals of manganic alum by an ethereal soln. of ferric chloride. B. Gossner and M. Arm prepared a potassium manganic oxysulphate, analogous to voltaite, and hence called **manganivoltaite**. O. T. Christensen prepared **rubidium manganic tetrasulphate** as a *tetracosihydrate*, or *rubidium manganic alum*, $Rb_2SO_4.Mn_2(SO_4)_3.24H_2O$, or $RbMn(SO_4)_2.12H_2O$, by the method employed for the ammonium manganic alum. The salt rapidly loses water of crystallization at ordinary temp. A. Piccini electrolyzed, at 0° to 15°, a soln. of equal parts of manganous and cæsium sulphates in 15 times their weight of 25 per cent. sulphuric acid. A platinum anode was used. The cathode liquor consisted of 25 per cent. sulphuric acid and was separated by a parchment diaphragm. A coral-red, crystalline powder of **cæsium manganic tetrasulphate** as a *tetracosihydrate*, or *cæsium manganic alum*, $Cs_2SO_4.Mn_2(SO_4)_3.24H_2O$, was thus obtained. O. T. Christensen also prepared the salt by the process used for the ammonium manganic alum, but working at 0° to 5°. The coral-red crystals belong to the cubic system. Their refractive index for red light is 1·4466 to 1·4793. The crystals are decomposed by water with the separation of hydrated manganic oxide. They form a brown soln. with cold hydrochloric acid ; with dil. sulphuric acid they form a wine-red soln. ; and with conc. sulphuric acid, a violet-red soln. A. Piccini said that the salt melts in its water of crystallization at 40°, but it loses water below this temp. The crystals can be preserved in a closed vessel at ordinary temp., but not in air. J. L. Howe and E. A. O'Neal said that they were unable to prepare ammonium, rubidium, and cæsium manganic alums by the electrolytic process. O. T. Christensen obtained **thallous manganic tetrasulphate** as a *tetracosihydrate*, or *thallous manganic alum*, $Tl_2SO_4.Mn_2(SO_4)_3.24H_2O$, or $TlMn(SO_4)_2.12H_2O$, as a coral-red crystalline powder, by the method employed for ammonium manganic alum.

A. Étard prepared **aluminium manganic trisulphate**, $Mn_2(SO_4)_3.2Al_2(SO_4)_3$, or $MnAl(SO_4)_3$, by heating at 250° a conc. soln. of manganous and aluminium sulphates, in the theoretical proportions, with a mixture of equal vols. of sulphuric and nitric

acids. The violet soln. deposits the salt in a short time as a blue crystalline pre-
cipitate which is sparingly soluble in water, and it is decomposed by that liquid.
He also obtained **chromium manganic trisulphate,** $Mn_2(SO_4)_3.Cr_2(SO_4)_3$, or
$MnCr(SO_4)_3$, as a green crystalline precipitate, by oxidizing manganous sulphate
with chromic acid in the presence of sulphuric acid, as in the case of the aluminium
manganic sulphate. If the soln. of chromium manganic sulphate be cooled before
crystallization occurs, the salt crystallizes out with a mol. of sulphuric acid to form
chromium manganic trisulphatohydrosulphate, $CrMn(SO_4)_3.H_2SO_4$, in brown
plates. A similar compound with ferric sulphate (q.v.) was formed.

E. Frémy, C. F. Böhringer, W. Lang, H. Merzbach and J. F. Smith, and K. Puls
regarded **manganese disulphate,** $Mn(SO_4)_2$, as well as manganic sulphate,
$Mn_2(SO_4)_3$, as intermediate products of the reduction of potassium permanganate
dissolved in conc. sulphuric acid. M. Sem said that soln. of manganous sulphate
in dil. sulphuric acid when electrolyzed with a double anode—one plate of
manganese and one of platinum—furnished a soln. of manganese disulphate. It
is also said that soln. of manganous sulphate are oxidized according to the scheme :
$MnSO_4 \rightarrow Mn_2(SO_4)_3 \rightarrow Mn(SO_4)_2 \rightarrow [Mn_2(SO_4)_7] \rightarrow HMnO_4$. A. N. Campbell did not
observe the formation of the disulphate in his study of the electrolysis of sulphuric
soln. of manganous sulphate. For G. Grube and K. Huberich's observations on
the oxidation potential, and the hydrolysis of this salt, *vide supra*, manganous
sulphate. According to F. Weckbach, the disulphate cannot be isolated, and it
exists only in soln. of sulphuric acid. The Badische Anilin- und Sodafabrik found
that sulphuric acid of sp. gr. 1·384 dissolves 15 per cent., and an acid of sp. gr. 1·616,
4 to 5 per cent. F. Weckbach observed that if the soln. be well cooled, crystals of
$Mn_2(SO_4)_3.H_2SO_4.8H_2O$ are formed. E. Frémy obtained an acid salt of quadri-
valent manganese by the action of 70 per cent. sulphuric acid on potassium per-
manganate ; which was for a time regarded as manganic disulphate, $Mn(SO_4)_2$.
It is probably an oxysulphate. The Badische Anilin- und Sodafabrik obtained a
basic salt, **manganese oxysulphate,** $MnO_2.SO_3$, or $MnO(SO_4)$, by electrolyzing a
soln. of manganous sulphate in sulphuric acid, at about 60°, by means of a lead
cathode in sulphuric acid ; the anode may be of lead, but if it be manganese or
ferromanganese, a salt of manganese need not be dissolved in the acid, which is then
used in a more concentrated state than before. In another process, a hot sulphuric
acid soln. of manganous sulphate is treated with lead dioxide ; or 70 per cent.
sulphuric acid is added to a mixture of potassium permanganate and sodium
sulphate. The salt is obtained in the solid state by separately adding powdered
manganous sulphate and potassium permanganate to hot 55 per cent. sulphuric
acid ; on cooling the salt separates as a black mass. The salt and soln. are decom-
posed by water ; and when the sulphuric acid soln. is poured into fuming sulphuric
acid, manganic sulphate is precipitated and oxygen is evolved.

According to E. Frémy, if a conc. soln. of manganous sulphate be poured into
a soln. of manganese oxysulphate, hexagonal plates of a **manganese tetrasulphate,**
$MnO.MnO_2.4SO_3.9H_2O$, or $MnSO_4.Mn(SO_4)_2.H_2SO_4.8H_2O$, are formed ; and also
by adding alcohol to the same soln. O. T. Christensen obtained the salt by the
action of sulphuric acid on manganic acetate or phosphate. According to E. Frémy,
the deliquescent crystals are decomposed by heat, water, and paper, and must
therefore be freed from the mother-liquor by pressure on a porous tile. The salt
forms a rose-coloured soln. with dil. sulphuric acid ; it is decomposed by alkalies,
and the precipitate gives up a good proportion of manganous oxide to a soln. of an
ammonium salt. The salt is not therefore a manganic sulphate.

When warm and moderately conc. sulphuric acid is treated with potassium
permanganate until no more salt is dissolved, and the mixture is heated, claret-
red crystals of **potassium manganic henicosisulphate,** $5K_2SO_4.2Mn_5(SO_4)_8$, are
formed. The crystals are washed with absolute alcohol, and ether, and dried at
ordinary temp. This salt dissolves in dil. sulphuric acid to form a brown soln.,
and in conc. sulphuric acid to form a violet-blue soln. ; and it decomposes on

heating into potassium and manganous sulphates, oxygen, and sulphur dioxide ; and when treated with much water it furnishes a soln. of manganous sulphate and hydrated manganese dioxide. B. Franke represented it by the formula $Mn=(SO_4)_2=(Mn)_3=(SO_4)_2=Mn.5K_2SO_4$. N. Bjerrum and G. H. Hansen could not prepare a chromic manganic halogenosulphate like those obtained with tervalent aluminium, chromium, and iron.

§ 24. Manganese Carbonates

In 1782, T. Bergman [1] referred to a *magnesium acido aereo mineralisatum* ; D. G. J. Lenz, 12 years later, to *Luftsaures Braunsteinerz* ; and R. J. Haüy, to *manganèse oxydé carbonaté*. These minerals were **manganous carbonate,** $MnCO_3$, and in the last part of the eighteenth century the mineral carbonate was in many cases confused with the silicate. The carbonate received many other names. Thus, A. Breithaupt called it *Rosenspat*, and *Himbeerspat* ; A. G. Werner, *Manganspat*—manganese spar—and *Roter Braunstein* ; F. Mohs, *makrotyper Parachrosbaryt*, and *isometrischer Parachrosbaryt* ; and J. F. L. Hausmann, *Dichter Rotspat*, and also **rhodochrosite**—from ρόδον, a rose, and χρώσις, colour. C. F. Jasche, and E. F. Germar called it *dialogite*—from διαλογή, doubt ; and F. S. Beudant, *diallogite*. E. Dittler described pebbles of *manganodolomite* from the Enns, Upper Austria. Analyses of the mineral were reported by L. Baric and F. Tucan, C. Bergemann, P. Berthier, A. Birnbacher, P. E. Browning, A. Bukowsky, V. C. Butureanu, G. Flink, H. von Foullon, A. Frenzel, C. L. Gruner, T. Haege, E. Hildenbrand, T. S. Hunt, C. von John, R. J. Kane, G. A. Kenngott, C. M. Kersten, L. L. de Koninck, F. Kossmat and C. von John, K. von Kraatz-Koschlau, J. A. Krenner, F. Kretschmer, G. F. Kunz, A. Lacroix, M. Lienau, H. Ludwig, E. Manasse, F. Millosevich, W. Ortloff, S. L. Penfield, P. Poni, F. Sandberger, F. Sansoni, A. Schwager and C. W. von Gümbel, M. von Sill, F. Stromeyer, V. Vesely, E. T. Wherry and E. S. Larsen, K. Zimanyi, and H. Zinkeisen. Iron carbonate is usually present ; sometimes the carbonates of calcium, magnesium, and zinc ; and rarely cobalt carbonate.

The *manganosiderite* of F. Bayer is a variety of siderite containing manganese carbonate ; a calcareous variety described by W. T. Roepper was called *roepperite* by G. A. Kenngott ; other calcareous varieties described by A. des Cloizeaux, J. A. Krenner, C. F. Rammelsberg, A. Bukowsky, and M. Weibull were called *manganocalcite* ; a zinciferous variety was called *zinc rhodochrosite* by E. Manasse ; and a ferruginous variety was called *ponite*—after P. Poni—by V. C. Butureanu. M. Lienau called a variety from Vielle Aure, *viellaurite* ; another variety from Vielle Aure, *torrensite* ; another variety from Vielle Aure, *lacroisite*— after A. Lacroix ; another variety from Vielle Aure, *schokoladenstein* ; and one from Huelva, *huelvite*. These five varieties of M. Lienau are probably mixtures. A. Bukowsky described large, cleavable masses of a white mineral with a rosy tinge which he called *kutnohorite* ; its composition corresponds with $7CaCO_3.5MnCO_3.FeCO_3.2MgCO_3$.

Pseudomorphs of rhodochrosite after various minerals have been examined by A. E. von Reuss, J. R. Blum, V. R. von Zepharovich, A. Frenzel, and E. Döll ; and the mode of formation of the mineral in nature has been discussed by A. Bergeat, and F. Kossmat and C. von John. Manganese carbonate imitating the mineral was prepared by H. de Sénarmont by heating a mixture of manganous chloride and calcium carbonate in a sealed tube at 150° for 18 hrs. ; by treating manganous chloride with sodium carbonate at 160° ; and by slowly driving carbon dioxide from a mixed soln. of manganous chloride and sodium hydrocarbonate saturated with carbon dioxide. The pale pink crystals so formed have a composition corresponding with $MnCO_3$. F. Hoppe-Seyler obtained microscopic rhombohedra of manganous carbonate by the action of calcium carbonate on a soln. of manganous sulphate at 200°. E. Weinschenk obtained similar crystals by heating a mixture of manganous sulphate and urea at 160° to 180° for an hour. A. de Schulten obtained small crystals whose analysis agreed with $MnCO_3$ by the action of ammonium carbonate on a soln. of manganous chloride heated on a water-bath ; and also by warming a soln. of manganous carbonate in water saturated with carbon dioxide. The anhydrous salt was also obtained by dehydrating the hydrated carbonate ; L. Joulin said that if the hydrated salt is precipitated by sodium carbonate in the cold, and dried at 60°, over quicklime, its composition is $MnCO_3$.

R. Laming, and E. Prior obtained **hydrated manganous carbonate** by treating a manganous salt soln. with ammonium carbonate ; and H. Tamm, and C. R. Fresenius noticed that even if ammonium chloride be present, the precipitation is complete. R. Laming also observed that a precipitate of manganous carbonate containing no hydroxide is produced by sodium hydrocarbonate ; and E. Prior added that the precipitation with sodium hydrocarbonate occurs only when the soln. has stood for some time, and carbon dioxide is given off. H. Moissan prepared the hydrated carbonate by adding sodium hydrocarbonate to a soln. of manganous chloride saturated with carbon dioxide, and washing the product with water saturated with carbon dioxide. According to R. Laming, if the precipitant sodium carbonate is not in excess, manganous carbonate alone is precipitated, but if an excess is employed, the precipitate loses some carbon dioxide to form sodium hydrocarbonate ; but E. Prior added that manganous carbonate alone is precipitated with or without an excess of sodium carbonate provided air be excluded, but if air be present some hydrated manganosic oxide is precipitated as well as manganous carbonate. According to A. Ure, E. Turner, and E. Prior, the composition of the precipitated carbonate, dried in vacuo, is the *hemihydrate*, $2MnCO_3.H_2O$; and if dried in air, G. Forchhammer, and E. Prior found the composition is the *monohydrate*, $MnCO_3.H_2O$. J. Lefort said that if manganous carbonate is precipitated from a hot or cold soln. of a manganous salt by alkali carbonate or hydrocarbonate, the composition is $MnCO_3.H_2O$. According to H. Rose, the precipitate obtained with soln. containing a mol of sodium carbonate and a mol of manganous sulphate, each in 10 parts of water, has the composition of $MnO.8CO_2.5H_2O$ if precipitated from cold soln., and $11MnO.10CO_2.4H_2O$ if precipitated from hot soln. ; if the two soln. contain ten times as much water, the precipitates with cold and hot soln. have the compositions respectively $9MnO.8CO_2.5H_2O$ and $6MnO.5CO_2.2H_2O$.

According to L. Joulin, when soln. of manganous chloride, sulphate, or nitrate

are treated with sodium carbonate, the precipitate may be manganous hydroxide or carbonate or a mixture of the two, according to the conditions. If the manganous salt soln. be poured into the soln. of sodium carbonate at ordinary temp. with equimolar parts of the two salts and dilutions up to 1 : 200, flocculent manganous carbonate is precipitated ; but with higher dilutions the precipitate will contain manganous hydroxide and this the more the greater the dilution. The filtrate contains sodium hydrocarbonate. The precipitate remains white if air be excluded, but it becomes brown on exposure to air. If the sodium carbonate be in excess and very conc. soln. are used, manganous hydroxide is formed, and this is also the case when the conc. manganous salt soln. is dropped on solid sodium carbonate ; if the action occurs in vacuo, carbon dioxide is evolved, and re-absorbed by the soln. of sodium carbonate to form hydrocarbonate. If the manganous salt be in excess and conc. soln. are employed, manganous carbonate is formed ; but if the dilution exceeds 1 : 500, some manganous hydroxide is formed, and this the more the greater the dilution. Only a trace of hydroxide is formed at 0° if 40 mols. of sodium carbonate are present per mol. of manganous salt ; but at 100° 3 mols. of manganous carbonate per mol. of sodium carbonate must be present in order to obtain manganous carbonate alone—if equimolar proportions are present, appreciable quantities of hydroxide are formed. The formation of the precipitate occupies a certain time ; with equimolar parts and a dilution of 1 : 1000, the proportions of sodium carbonate decomposed are :

	1	2	4	7	15	30 days
Na$_2$CO$_3$ decomposed .	76·85	79·88	86·56	87·28	92·67	94·90 per cent.

The speed of the reaction is retarded by reducing the concentration of the soln. ; by the presence of sodium sulphate ; by reducing the temp. ; and by adding an excess of either reacting salt—*vide infra*, the hydrolysis of the carbonate. H. W. Morse observed evidence of a periodicity in the precipitation of the carbonate. W. E. Adeney reported the reduction of manganese dioxide to manganous carbonate by bacterial fermentation.

The **colour** of rhodochrosite may be various shades of pink, yellowish-grey, fawn, dark red, or brown. The powder or streak is white. The artificial crystals obtained by A. de Schulten were almost colourless. The hydrate is snow-white, tasteless, and stable in air. Distinct crystals are not common, and when they are, the form is usually rhombohedral, with more or less rounded and striated faces. Rhodochrosite occurs also in compact, granular, or cleavable masses ; it may be globular or botryoidal with a more or less distinct columnar structure ; and it may occur as an incrustation on other minerals. According to F. Sansoni, the **crystals** are scalenohedral and trigonal with the axial ratio $a : c = 1 : 0·81840$, while A. de Schulten gave 1 : 0·8259, and $\alpha = 102° 50'$. F. Rinne found that the normal angle of the (100)-face is 73° 4′ 8″ at 16° ; 73° 10′ 14″ at 115° ; and 73° 15′ 38″ at 212°. The axial ratio was $a : c = 1 : 0·8147$ at 16° ; and 1 : 0·8232 at 212°. At 300° the crystals broke into pieces. N. Sundius gave 73° 2′ for the cleavage angle. The (101)-**cleavage** is perfect. Observations on the crystals were made by C. F. Peters, F. Sandberger, A. des Cloizeaux, R. Nostiz, K. von Kraatz-Koschlau, S. Koch, G. Greim, A. Reis and L. Zimmermann, F. Ritter, E. Weiss, A. von Lasaulx, P. Groth, O. Luedecke, J. S. Presl, V. R. von Zepharovich, F. Millosevich, H. Berman and F. A. Gonyer, C. L. Gruner, and G. Flink. A. Lacroix found **twinning** about the (110)-plane ; S. Kreutz studied the **over-growths** ; I. N. Stransky and K. Kulelieff, the growth of the crystals ; and G. Tschermak found that the **corrosion figures** resembled those of magnesite ; and A. Honess, that they are like those of calcite when the crystals are treated with salt soln. and with dil. nitric acid. P. Leroux said that the mineral is pleochroic. The crystals may have **inclusions** of pyrite, wad, limonite, etc. A. Johnsen observed the (111)-plane is a **gliding plane** under a press. of 7000 atm., and K. Veit obtained a similar result at 12,000 atm. press. According to P. P. Ewald, J. Brentano and J. Adamson,

and W. L. Bragg, the **X-radiograms** agree with a trigonal structure of the calcite-type ; and R. W. G. Wyckoff found that the length of the side of the unit rhombohedron is $a=6.03\times10^{-8}$ cm. ; and the angle between the axes is $a=47°$ 46' ; C. Mauguin gave $a=3.755\times10^{-8}$ cm., and $a=77°$ 59'. M. L. Huggins, G. R. Levi, and P. Niggli discussed the electronic structure of the crystals. P. Krieger studied the X-ray diffraction patterns of the manganocalcites, and concluded that the spacing of the atomic planes varies from 3.075 A. for calcite to 2.850 A. for rhodochrosite. The atomic planes are therefore more closely packed in the manganese minerals ; and since the manganese and calcium atoms provide the only variables in the series, the variation is due to the replacement of calcium atoms by manganese atoms in the atomic structure. J. E. Lennard-Jones and B. M. Dent calculated the energy required to separate a mol of a crystal into its ions, and found 750 cals. G. Bilibin discussed the isomorphism of the salt.

The **specific gravity** of rhodochrosite given by T. S. Hunt is 3.25 ; V. Vesely gave 3.312 to 3.552 ; C. M. Kersten, 3.533 ; F. Stromeyer, 3.557 ; C. L. Gruner, 3.570 to 3.61 ; L. Baric and F. Tucan, 3.570 to 3.698 ; E. Madelung and R. Fuchs, 3.663 ; F. Sandberger, 3.59 ; A. Krantz, 3.660 ; O. B. Böggild, 3.666 ; and G. J. Brush and E. S. Dana, 3.76. A. de Schulten gave 3.65 for the sp. gr. of the artificial crystals. P. Krieger found the following values for the sp. gr., the refractive indices, and the spacing d_{100} of a unit rhombohedron of a series of manganocalcites :

$MnCO_3$	.	0	1.09	7.00	15.40	32.34	42.17	95.72 per cent.
Sp. gr.	.	2.715	2.724	2.824	2.856	3.021	3.143	3.710
ϵ	.	1.486	1.490	1.501	1.503	1.519	1.534	1.595
μ .	.	1.658	1.662	1.672	1.680	1.713	1.721	1.817
d_{100}	.	3.075	3.055	3.020	3.005	2.975	2.948	2.850 A.

H. G. F. Schröder gave 3.13 for the monohydrate at 3.9°. N. Sundius examined the systems $CaCO_3$–$MnCO_3$, and $CaMg(CO_3)_2$–$Ca(Fe,Mn)(CO_3)_2$, and measured their sp. gr. The sp. gr. of manganese carbonate is 3.691. I. I. Saslawsky studied the contraction which occurs in the formation of the carbonate from its elements. The **hardness** of the crystals of rhodochrosite is given as 3.5 to 4.5 ; and F. Pfaff gave 25 for the scratching hardness on the (111)-face, and 43 on the (100)-face, when the hardness of steatite is unity. E. Madelung and R. Fuchs gave 1.3×10^{-6} megabars per sq. cm. for the compressibility of the carbonate. E. Jannetaz found the square root of the ratio of the **thermal conductivities** in directions parallel and vertical to the principal axis is 1.06 ; and the crystals are thermally negative.

L. Joulin studied the **dissociation pressure** of manganous carbonate ; he found that the salt dried at a low temp. in an atm. of carbon dioxide begins to decompose at 70° ; at 150° the press. of the carbon dioxide is 215 mm., which remains constant at that temp. If the salt be allowed to cool, the press. slowly returns to its initial value. Above 200° the press. rises to 2 atm., the carbonate becomes brown in colour, and no re-absorption of the gas occurs on cooling. If the carbonate be heated to 100° and allowed to cool, the press. of the gas on a second heating is less than half that attained during the first heating ; while a third heating gave virtually the same value for the press. as that obtained during the second heating. There was no exhaustion of the gas during these successive heatings, and the phenomenon is explained by assuming that the carbonate suffers an inter-molecular change which renders it more stable and more resistant towards decomposition at low temp. It must also be remembered that the carbon dioxide may be reduced by the manganous oxide, so that a complex series of equilibria is involved. Thus, $MnCO_3 \rightleftharpoons MnO + CO_2$; $3MnO + CO_2 \rightleftharpoons Mn_3O_4 + CO$; and $2MnO + CO_2 \rightleftharpoons Mn_2O_3 + CO$. W. Manchot and L. Lorenz found that the dissociation press. of manganous carbonate and the re-absorption of the carbon dioxide depend on the water-content of the specimen, and is a result of hydrolysis. The process is reproducible only with samples containing an equal proportion of water. All precipitated manganous carbonate retains water up to complete decomposition. J. Lefort's

statement that the hydrate can be dehydrated at about 70° is wrong; H. Rose also noted how water is retained with great tenacity even after the carbonate has lost some carbon dioxide. W. Manchot and L. Lorenz observed that a specimen of rhodochrosite gave a lower press. than the artificial carbonate, but if moistened it reacted similarly but to a less extent. There is no evidence that a definite basic carbonate is formed. K. Friedrich and L. G. Smith found that a sample of rhodochrosite from Colorado commences to decompose at 525°, and the maximum decomposition occurs at 570°, while with a sample from Peru decomposition commences at 510° and attains a maximum at 550°. In both cases decomposition was practically complete at 700°. A. Beutell and P. Oberhoffer found that a sample from Freiburg suffered an appreciable decomposition at 300°. K. Grünberg found that the losses in weight of a sample of native manganese spar heated in a current of air were 0·45 per cent. in 3 hrs. at 300° and 360°—this loss is mainly water; 0·86 per cent. in 3 hrs. at 400°; 2·09, 9·56, and 41·60 per cent. in respectively 3, 9, and 12 hrs. at 470°; while in a current of carbon dioxide there was no loss at 360° or 400° during 3 hrs.; at 530° there was a loss of 0·13 per cent. in 12 hrs.; 0·39 per cent. in 3 hrs. at 570°; 1·59 per cent. in 3 hrs. at 590°; and 8·33 per cent. in 24 hrs.; while at 650° there was a loss of 10·58 per cent. in 3 hrs., and of 40·61 per cent. in 6 hrs. J. A. Hedvall said that dissociation begins at about 395° and is complete at 595°. With W. Nernst's theorem, O. Brill calculated for the dissociation pressure, p, of the carbonate at $T°$ K., log $p=23500/4\cdot571T+1\cdot75$ log $T+3\cdot2$, so that for a dissociation press. of one atm. the calculated dissociation temp. is 359° or 632° K.; L. Joulin found 327°. According to M. Berthelot, the **heat of precipitation** of manganous carbonate from a soln. of manganous chloride by potassium carbonate is —4·0 Cals., and the precipitate is amorphous. It develops in consequence of crystallization 1·6 Cals. This value is independent of the first. If a soln. of sodium carbonate is employed, the data are respectively —3·7 Cals. and 1·4 Cals. H. le Chatelier observed that in a calorimetric bomb $3MnCO_3+O$ $=Mn_3O_4+3CO_2-27\cdot8$ Cals. M. Berthelot calculated for the **heat of formation** of crystalline manganous carbonate $(Mn,C,3O)=208\cdot6$ Cals.; of the amorphous carbonate, 207·0 Cals.; and of the natural carbonate, 212·7 Cals. Again, $Mn(OH)_2+CO_2+Aq.$ $=MnCO_3+Aq.+12\cdot0$ Cals. for amorphous carbonate, and 13·6 Cals. for the crystalline carbonate. Similarly, $CO_{2gas}+Mn(OH)_2=MnCO_{3cryst.}+H_2O+19\cdot2$ Cals.; and $CO_{2gas}+MnO=MnCO_{3cryst.}+23\cdot5$ Cals.; and D. Müller, 27·7 Cals., or $(Mn,C,1\frac{1}{2}O_2)=218\cdot2$ Cals. J. Thomsen gave $(Mn,O,CO_2)=113\cdot88$ Cals.; and $(Mn,3O,C)=181\cdot84$ Cals.; W. A. Roth, 218·2 Cals.; and H. le Chatelier, (MnO,CO_2) $=276$ Cals.; and W. A. Roth, 279 Cals. J. C. W. Frazer and C. E. Greider gave $MnO+CO_2=MnCO_3+5\cdot5$ Cals. G. Beck discussed the energy of formation.

The **indices of refraction** of different samples of rhodochrosite were found by P. Gaubert to range from $\omega=1\cdot7941$ to $1\cdot8194$, and $\epsilon=1\cdot5946$ to $1\cdot6023$; E. T. Wherry and E. S. Larsen, $\omega=1\cdot817$, and $\epsilon=1\cdot594$; W. Ortloff, $\epsilon=1\cdot5973$; W. E. Ford, $\omega=1\cdot8279$, and $\epsilon=1\cdot5904$ to $1\cdot6057$; and N. Sundius, for Na-light, $\epsilon=1\cdot600$, and $\omega=1\cdot816$. The subject was discussed by P. Niggli—*vide supra.* W. A. Wooster discussed the relation between the refractive index and the lattice structure. W. Ortloff gave 19·43 for the **refraction equivalent.** The **birefringence** is strong; and the **optical character** negative. A. Madelung observed a feeble **optical anomaly** with a sample of rhodochrosite. There is strong **pleochroism**, and G. F. Kunz reported a sample with the ordinary ray pink and the extraordinary ray pale yellow. W. W. Coblentz found that rhodochrosite showed maxima in the **ultra-red reflection spectrum** at 6·63μ, 11·47μ, and 14·0μ. C. Doelter observed that the exposure of rhodochrosite to **radium radiations** has scarcely any effect on the colour. E. Engelhardt observed that some varieties have a red and others a green fluorescence under the action of **ultra-violet light.** O. Stelling studied the K-series of **X-ray absorption**; G. Dupouy, the **magnetic properties**; and W. Sucksmith, the **gyromagnetic effect.**

J. A. Arfvedson found that when manganous carbonate is heated in **hydrogen,**

manganous oxide is formed. E. R. Schneider found that when the carbonate is heated to redness in **oxygen** it forms manganic oxide ; and F. Hoppe-Seyler, that with oxygen and steam at 200° anhydrous manganosic oxide is formed. The weathering of rhodochrosite in nature was discussed by A. Bergeat, and F. Kossmat and C. von John. A. Gorgeu observed that when the dry carbonate is heated in **air**, it primarily forms manganous oxide, which then forms a higher oxide—manganic oxide at below 425°. F. Hoppe-Seyler observed that oxygen and water-vapour at 200° transform it into manganosic oxide. A. Gorgeu found that at ordinary temp. the oxygen of air—moist or dry—gradually attacks hydrated manganous carbonate, forming manganic oxide and no higher oxide ; hence, he argued that the manganese dioxide minerals were not formed by the oxidation of the carbonate, as had been supposed by J. B. J. D. Boussingault, and L. Dieulafait. M. W. Beyerinck did not notice any particular tendency of manganous carbonate to oxidize in air, for he was able to keep an aq. suspension for years without taking any special precautions, and manganous carbonate agar-agar plates may be kept unchanged for months with free access of air. When two pieces of filter paper with a little manganous carbonate between them, and moistened with a dil. soln. of ammonium chloride and potassium phosphate, are infected with garden soil and kept at about 25°, dark brown or black spots of a manganic compound will appear on them after some days. The characteristic reactions of the manganic compound thus produced are the sudden decomposition of hydrogen dioxide and the oxidation of hydriodic acid. Bacteria and various species of mould are the cause of the oxidation. These moulds belong to very different groups of the fungi, and consist of species of the genera *Botrytes, Sporocybe, Trichocladium,* and in particular of *Mycogone*. Oxidation appears to occur as well within as without the mycelium. It could not be brought about by oxydase or peroxydase of different origin. H. Rose said that the carbonate begins to oxidize at 150°, and becomes dark brown at 200° ; J. Lefort found that the carbonate oxidizes at 300° ; and G. Forchhammer, at 260°. W. Reissig found that more oxygen is absorbed the longer the time the carbonate is heated in air and the higher the temp., short of 300° ; at that temp. the residue approximates $MnO.2MnO_2$. L. Joulin said that cold **water** does not decompose manganous carbonate, but if the water be boiled with the carbonate for a long time, some manganous hydroxide is formed and subsequently oxidized. J. L. Lassaigne said that hydrated manganous carbonate is insoluble in water, but it is soluble in water containing carbon dioxide in soln.—the **solubility** in 100 parts of water saturated with that gas is 0·05 part of $MnCO_3$. C. von John added that 100 parts of water dissolve 0·013 part of the carbonate, while 100 parts of water with carbon dioxide in soln. dissolve 0·026 part of carbonate. These observations are not precise enough with respect to the concentration of the carbon dioxide. According to F. Ageno and E. Valla, a litre of water at 25° dissolves 0·065 grm. of manganous carbonate. Following G. Bodländer's observations on the carbonates of the alkaline earths, and also the observations of J. Walker and W. Cormack, and of F. Auerbach and H. Pick, it follows that in aq. soln. the following equilibria are involved : $[Mn^{..}][CO_3'']=K_1$; $[H^.][HCO_3']=K_2[H_2CO_3]$, where $K_2=3\times10^{-7}$; $[H^.][CO_3'']=K_3[HCO_3']$, where $K_3=6\times10^{-11}$; and $[H_2CO_3]=K_4p$, where K_4 $=0·03388$, and the partial press. of the carbon dioxide, p, is expressed in atm. On account of the small dissociation of the HCO_3'-ions, and the almost complete dissociation of the manganous hydrocarbonate, $2K_1K_2K_4p=K_3[HCO_3']^3$; and $K_1^{\frac{1}{2}}=0·143[HCO_3']p^{-\frac{1}{2}}$. F. Ageno and E. Valla found at 25° :

p	.	.	0·8217	0·6367	0·5298	0·5228	0·3277	0·3296
s	.	.	0·003103	0·002647	0·002531	0·002240	0·002171	0·002255
$K_1^{\frac{1}{2}}$	.	.	0·000473	0·000439	0·000447	0·000397	0·000450	0·000466

The mean value for $K_1^{\frac{1}{2}}=4·45\times10^{-4}$, so that the **solubility product** of manganous carbonate at 25° is $K_1=8·83\times10^{-11}$. Water alone, at 25°, dissolves $5·659\times10^{-4}$ mol. per litre at 25°, and consequently for the hydrolysis $CO_3''+H_2O\rightleftharpoons HCO_3'$

$+OH'$, $[Mn\cdot\cdot][CO_3'']=K_1$; or $K_1/[Mn\cdot\cdot]=8\cdot83\times10^{-11}/5\cdot659\times10^{-4}=1\cdot56\times10^{-7}$; and $[HCO_3']=5\cdot659\times10^{-4}-0\cdot00156\times10^{-4}=5\cdot657\times10^{-4}$, which is virtually the same as that of $[Mn\cdot\cdot]$. This means that the degree of **hydrolysis** of manganous carbonate in aq. soln.: $MnCO_3+H_2O=Mn(OH)(HCO_3')$, is virtually 100 per cent. The soln. of manganese carbonate in water sat. with carbon dioxide contains **manganese hydrocarbonate,** $Mn(HCO_3)_2$. E. Dittler found that quartz sand adsorbs 51·74 per cent. of the manganese in soln.; china clay, 68·73 per cent.; compact limestone, 72·9 per cent.; marl, 78·53 per cent.; and chalk, 96·53 per cent. In the last case there was probably some chemical replacement of calcium by manganese. O. Haehnel found the solubilities of the manganese carbonate under a pressure of 8 and 56 atm. to be respectively 0·04 and 0·08 per cent. R. Lyden obtained for the solubility of rhodochrosite 0·0127 grm. Mn_3O_4 per 500 c.c., a value rather smaller than that usually accepted. L. Gmelin said that a boiling soln. of **potassium hydroxide** extracts carbon dioxide and forms manganous hydroxide; a soln. of **sodium carbonate** in the presence of air was found by R. Laming to form a brown hydrated manganic oxide and sodium hydrocarbonate; and L. Joulin added that the action is extremely slow at 0°, but rapid at 100°. J. J. Ebelmen said that manganous carbonate is no more soluble in a soln. of alkali carbonate than it is in water alone. L. Joulin found that a soln. of **sodium hydrocarbonate** changes manganous carbonate only after a few days. *Vide supra* for H. Rose's basic salts or **manganous oxycarbonates.**

F. Wöhler represented the reaction with rhodochrosite and **chlorine,** at a red-heat, by $4MnCO_3+Cl_2=MnCl_2+Mn_3O_4+4CO_2$. R. Weber noticed that the action on the hydrated carbonate is very slow at ordinary temp. As previously indicated, A. Gorgeu found that chlorine, or chlorine water, acts on manganous carbonate suspended in water, forming one of the higher oxides with the expulsion of carbon dioxide; **bromine,** or bromine water, acts similarly but more slowly. R. Böttger obtained a similar result by the action of a boiling soln. of **calcium hypochlorite.** Manganous carbonate is soluble in **acids** generally. J. A. Arfvedson found that when the carbonate is heated to redness with twice its weight of **sulphur,** sulphur and carbon dioxides are given off and manganese sulphide, accompanied by a little oxide and sulphate, is formed; H. Rose observed that when heated to redness with powdered sulphur in hydrogen, manganese sulphide is formed. A. Voelcker noted that **hydrogen sulphide** gives no precipitate with a soln. of manganous carbonate in carbonated water. P. de Clérmont and H. Guyot found that an excess of **ammonium sulphide** transforms manganous carbonate slowly into green manganous sulphide, while **alkali sulphides** form red manganous sulphide. C. W. Davis studied the solvent action of sulphurous acid. F. Muck did not get the same result with ammonium sulphide. E. C. Franklin and C. A. Kraus found that manganous carbonate is insoluble in liquid **ammonia.** R. H. Brett said that a soln. of the carbonate in an aq. soln. of **ammonium salts**—chloride or nitrate—does not give a precipitate with hydrogen sulphide, and G. C. Wittstein found that the freshly-precipitated carbonate is soluble in soln. of ammonium salts. H. Goldschmidt.and K. L. Syngros found that a soln. of manganese chloride and hydroxylamine hydrochloride forms a white precipitate with sodium carbonate; when washed and dried, the grey powder is **manganous hydroxylaminocarbonate,** $4MnCO_3.3NH_2OH.2H_2O$, soluble in acids. According to M. Flajlot, manganous carbonate is insoluble in a soln. of **potassium cyanide.** J. Spiller found that the carbonate is not precipitated in the presence of **sodium citrate;** and A. Naumann found that it is insoluble in **ethyl acetate.** D. Talmud and N. M. Lubman found that the flotability of manganese carbonate in **oleic acid** or mixtures of oleic acid and ammonia is a maximum for $p_H=7$. W. H. Coghill and J. B. Clemmer studied the soap flotation of rhodochrosite.

According to A. D. Brokaw, amorphous manganous carbonate reacts at once with **gold chloride** with production of the dark brown hydrated dioxide. Crystallized manganous carbonate acts slowly, but after a day becomes coated with the

dark brown hydrated oxide and flakes of gold. F. W. O. de Coninck exposed a mixture of a soln. of 2 mols of **sodium nitrate** and a mol of manganous carbonate to light for 5 months without any reaction taking place. J. N. von Fuchs observed that the carbonate dissolves in a soln..of a **ferric salt,** giving off carbon dioxide and precipitating ferric hydroxide.

G. C. Wittstein supposed that freshly-precipitated manganous carbonate dissolved in a soln. of ammonium carbonate is present as **ammonium manganous carbonate ;** and F. Ephraim obtained the salt $(NH_4)_2CO_3.MnCO_3.4H_2O$ in microscopic prisms. W. C. Reynolds prepared **potassium manganous carbonate,** $K_2Mn(CO_3)_2.4H_2O$, by the action of a cold soln. of potassium carbonate of sp. gr. 1·53 on manganous acetate and rubbing the mixture in a mortar. Crystals of the salt are quickly formed ; they are only sparingly soluble in water. If the mixture used in the preparation be warm oxidation occurs. O. Ruff and E. Ascher studied solid soln. of *manganese and calcium carbonates*. L. H. Bauer and H. Berman found radiating groups of lathe-shaped, bluish-black needles of **zinc manganese hydroxycarbonate,** $2(Zn,Mn)CO_3.5(Zn,Mn)(OH)_2$, occurring as a mineral which they called **loseyite**—after S. R. Losey. The composition recalls that of hydrozincite, $ZnCO_3.2Zn(OH)_2$. The monoclinic crystals have the axial ratios : $a : b : c = 0.70 : 1 : 0.62$, and $\beta = 94° 30'$. The optic axial angle $2V = 64°$; the optical character is positive ; the indices of refraction are $\alpha = 1.637, \beta = 1.648$, and $\gamma = 1.676$; the sp. gr. is 3·27 ; and the hardness about 3.

§ 25. The Manganese Nitrates

C. W. Scheele [1] first prepared **manganous nitrate**, $Mn(NO_3)_2$. It is obtained in soln. by dissolving manganous carbonate in nitric acid. According to J. F. John, manganese dioxide (*q.v.*) dissolves in nitric acid in the presence of reducing agents, which form some nitrous acid, or, according to C. W. Scheele, by exposing the system to sunlight, which decomposes some nitric acid into nitrous acid and oxygen. J. F. John obtained a soln. of the nitrate by dissolving the metal in hot nitric acid. J. W. Gatehouse obtained manganous nitrate by heating to 165° to 200° a mixture of manganese dioxide and ammonium nitrate. The evaporation of the aq. soln. furnishes a syrupy liquid which yields crystals of the hexahydrate. V. M. Peshkova described the preparation of the salt. A. Guyard noted the occurrence of manganous nitrate in native Chili saltpetre; and H. St. C. Deville and H. Debray found nitrates in native manganese dioxide.

J. M. Ordway found that at 25·8° the aq. soln. contains 62·4 per cent. of $Mn(NO_3)_2$ as hexahydrate. F. Rüdorff found that a soln. with 21·3 per cent. $Mn(NO_3)_2$ freezes at —10°. The following additional observations are due to R. Funk and co-workers, when the solubility S is expressed in percentages:

	—36°	—30°	—29°	—16°	0°	11°	**23·5°**	30°	35 5°
S	33·0	40·5	42·3	45·5	50·5	54·6	**64·6**	67·4	76·8
		$Mn(NO_3)_2.6H_2O$						$Mn(NO_3)_2.3H_2O$	

The results of R. Funk are plotted in Fig. 113. The ice-line and the solubility curve of the hexahydrate intersect at about —30°, but the **eutectic temperature** at —36° shows that a higher hydrate exists—and by analogy with the nitrates of related metals possibly a labile *enneahydrate*, $Mn(NO_3)_2.9H_2O$. J. F. John observed that the syrupy soln. crystallizes with difficulty at ordinary temp., furnishing acicular crystals, which, according to N. A. E. Millon, are those of the *hexahydrate*, $Mn(NO_3)_2.6H_2O$. A. Lührs and K. Kraut obtained the hexahydrate by evaporating the syrupy liquid over conc. sulphuric acid. Monoclinic, colourless crystals of the hexahydrate were also obtained by J. B. Hannay from its soln. in nitric acid. The crystals do not effloresce over sulphuric acid. R. Funk's Fig. 113 shows that the hexahydrate is stable between —30° and 25·8°; and

FIG. 113.—The Solubility of Manganous Nitrate.

at 25·8° water is given off owing to the formation of the *trihydrate*, $Mn(NO_3)_2.3H_2O$, so that the eutectic temp. between the tri- and hexahydrates is at 23·5°. E. Kordes discussed this eutectic mixture. A. C. Schultz-Sellack obtained the trihydrate by evaporating a soln. of the salt in conc. nitric acid in vacuo. The range of stability in aq. soln. is shown in Fig. 113. A. Ditte reported a *hemipentahydrate*, $Mn(NO_3)_2.2\frac{1}{2}H_2O$, and a *monohydrate*, $Mn(NO_3)_2.H_2O$, but the individual existence of the former has not been confirmed. A. Guntz and F. Martin obtained the monohydrate by melting the hexahydrate in its water of crystal-
lization and evaporating the product with the continuous addition of nitric acid, drop by drop. The cooled mass on soln. in nitric acid deposits pale pink deliquescent crystals. When the monohydrate so obtained is fused in an atm. of nitric anhydride, colourless or very faint pink crystals of the *anhydrous* salt are formed. J. W. Gatehouse's process indicated above also gives the anhydrous salt. A. Guntz and F. Martin also observed that the anhydrous nitrate can be obtained by treating with manganese a dry soln. of silver nitrate in a dry, non-aqueous solvent like acetone, benzonitrile, or liquid ammonia. The nitrate so obtained may form a complex with the solvent.

According to J. M. Ordway, the **specific gravity** of the hexahydrate crystals at 21° is 1·8199, and that of the undercooled hexahydrate which has been melted is 1·8104. A. C. Oudemans found the sp. gr. of aq. soln. at 8°/4° to be :

	5	10	15	20	30	40	50	60	71
$Mn(NO_3)_2.6H_2O$	1·0253	1·0517	1·0792	1·1078	1·1688	1·2352	1·3074	1·3861	1·4811

Observations were also made by G. T. Gerlach ; and J. Wagner found for N-, $0.5N$-, $0.25N$-, and $0.125N$-soln. of manganous nitrate at 25° the respective sp. gr. 1·0690, 1·0349, 1·0174, and 1·0093. For A. Heydweiller's observations, *vide infra*. A. N. Campbell found the sp. gr., the modulus, and electrostriction of the nitrate, as in the case of the chloride (*q.v.*), to be :

Eq. per litre	0·573718	0·344231	0·229395	0·114744	0·057372	0·022940	0·011474
Sp. gr. at 15°/15°	1·03685	1·02226	1·01493	1·00742	1·00367	1·00160	1·00085
$m_{\frac{1}{2}Mn} \times 10^4$	350	346	352	348	325	445	425
Electrostriction	−11·5	−10·5	−9·9	−10·0	−12·0	+7·0	+8·0

B. Cabrera and co-workers gave for soln. with C grms. of anhydrous salt per 1000 grms. of solvent, $C = 3.47 + 1179(D_{20}-1) - 560.7(D_{20}-1)^2$, where D denotes the sp. gr. For $C=480.9$, $D=1.5430\{1-0.00053(\theta-20)\}$; for $C=384.7$, $D=1.4023\{1-0.00047(\theta-20)\}$; for $C=183.2$, $D=1.1635\{1-0.00033(\theta-20)\}$; for $C=72.38$, $D=1.0597\{1-0.00024(\theta-20)\}$; for $C=39.70$, $D=1.0313\{1-0.00021-(\theta-20)\}$; and for $C=18.84$, $D=1.0138\{1-0.00020(\theta-20)-0.0_53(\theta-20)^{2.0}\}$. J. Wagner gave for the **viscosities** of N-, $0.5N$-, $0.25N$-, and $0.125N$-soln. at 25° the respective values 1·1831, 1·0867, 1·0426, and 1·0235 (water unity). C. A. Valson found for a tube 0·5 mm. diameter a **capillary rise** of 57·5 mm. at 15° for a soln. of sp. gr. 1·065. L. C. de Coppet, and F. Dreyer studied the capillarity of the soln. ; and G. Tammann, the internal pressure. J. C. Graham studied the **diffusion** of soln. of manganous nitrate. J. C. G. de Marignac found the **specific heat** of soln. with $Mn(NO_3)_2.nH_2O$, between 19° and 51°, to be 0·8320, 0·9027, and 0·9473 for soln. respectively with $n=50, 100$, and 200. K. Jauch, and N. de Kolossowsky discussed the subject. According to F. Rüdorff, the f.p. of water falls 0·116° per gram of the hydrate in 100 grms. of water. H. C. Jones and H. P. Bassett recorded a marked increase in the **lowering of the freezing-point** of soln. For small concentrations the mol. lowering corresponds with 5·55, the value for the ionization of the salt into these ions, but with more conc. soln. the high values are supposed to represent the formation of hydrates. For soln. with M mols of nitrate per litre, the lowering of the f.p. $\delta\theta$, and the mol. lowering of the f.p. Δ, are :

M	0·09	0·18	0·27	1·05	2·61	3·15
$\delta\theta$	0·46°	0·88°	1·41°	6·77°	27·25°	38·50°
Δ	5·11	4·89	5·22	6·45	10·44	12·22

According to H. St. C. Deville, anhydrous manganous nitrate decomposes at 200° into manganese dioxide and nitrous vapours. F. F. Beilstein made observations on this subject. R. Funk found that the **melting-point** of the trihydrate is 35·5°, and no decomposition occurs when the salt is fused. S. Jakubsohn and M. Rabinowitsch gave 25·8° for the m.p. of the hexahydrate ; and J. L. R. Morgan and P. T. Owen, 34·81°. J. F. John noted that the hexahydrate fuses easily, and at a higher temp. it decomposes into nitric acid fumes and leaves black manganic

oxide behind; R. Funk gave 25·8° for the m.p.—Fig. 113; and J. M. Ordway observed that the hexahydrate melts at 25·8°, and that the **boiling-point** is 129·5°, at which temp. it slowly decomposes. E. N. Gapon studied the relation between the b.p. and the sp. gr. J. L. R. Morgan and P. T. Owen calculated the **latent heat of fusion** of the trihydrate to be 28·09 cals. per gram. H. Lescoeur observed that the **vapour pressure** of a sat. soln. of the salt at 20° is 7·4 mm.; that of the dry hexahydrate at 20° is 3·9 mm.; and that of the efflorescent salt, $Mn(NO_3)_2$. $3\frac{1}{4}H_2O$, is 2·9 mm. at 20°. The hydrate slowly dissociates at this temp. At 70° the vap. press. of the sat. soln. is about 80 mm.; that of the partially dissociated hydrate, $Mn(OH)_2.3\frac{1}{4}H_2O$, is 85 mm.; and that of the trihydrate is 30 mm. This emphasizes the chemical individuality of the trihydrate. J. Thomsen gave for the **heat of formation** of manganous nitrate, $(Mn,N_2,3O_2,6H_2O)=153·7$ Cals.; $Mn+2HNO_{3aq.}=H_2+Mn(NO_3)_{2aq.}+117·72$ Cals.; for the **heat of neutralization**, $Mn(OH)_{2ppt.}+2HNO_{3aq.}=Mn'(NO_2)_{2aq.}+2H_2O+23·0$ Cals.; for the **heat of hydration**, $Mn(NO_3)_2+6H_2O=Mn(NO_3)_2.6H_2O+19·08$ Cals.; and the **heat of solution**, $Mn(NO_3)_2.6H_2O+400H_2O$, is $-6·15$ Cals., while A. Guntz and F. Martin gave for $Mn(NO_3)_2+280H_2O$, 12·93 Cals. J. Thomsen found the **heat of dilution**, Q, for a soln. of a mol of $Mn(NO_3)_2$ in ten mols of water, with n mols of water at about 18° to be:

n .	10	15	20	50	100	200	400
Q .	0	930	1294	1528	1541	1573	1648 cals.

H. C. Jones and F. H. Getman found the **indices of refraction**, μ, of soln. with M mols of $Mn(NO_3)_2$ per litre, to be:

M .	.	0·035	0·18	0·35	0·87	1·05	2·10	3·50
μ .	.	1·32554	1·32751	1·32949	1·33643	1·33768	1·34974	1·36459

R. Wachsmuth found that a soln. of 151·2 grms. of $Mn(NO_3)_2$ per litre has a sp. **magnetic rotation** of 0·1931 (water 0·99148) and a mol. magnetic rotation 1·9205. P. Krishnamurti discussed the **Raman effect** with manganous nitrate; and F. Allison and E. J. Murphy, the magneto-optic properties. S. Jakubsohn and M. Rabinowitsch found that the crystals of the hexahydrate had an **electrical conductivity** log $K=0·053130-0·73693$ in the undercooled state. A selection of the values for the salt is:

	$-15°$	$-8°$	$0°$	$11°$	$23°$	$26\,0°$	$40°$	$49°$
K .	$0·0_5228$	$0·0_5340$	$0·0_5623$	$0·0_41770$	$0·0_31080$	$0·0234$	$0·0374$	$0·0439$
			Solid				Molten	

The electrical conductivities, μ, of aq. soln. of a mol of manganous nitrate in v litres of water were measured by H. C. Jones and H. P. Bassett; and H. C. Jones and A. P. West's results are as follow:

v .	.	2	8	16	32	128	512	1024
	$0°$.	66·1	83·1	85·5	90·5	98·3	104·8	105·4
μ	$25°$.	116·3	144·3	154·5	165·0	182·0	196·6	195·8
	$35°$.	138·7	172·5	185·1	197·9	219·8	236·2	237·4
	$0°$.	62·7	78·8	81·1	83·9	93·3	99·4	100·0
α	$25°$.	59·4	73·7	78·9	84·3	93·0	99·4	100·0
	$35°$.	58·4	72·7	78·0	83·4	92·6	99·5	100·0

The calculated values for the percentage **degree of ionization**, α, are also indicated. A. Heydweiller gave for the sp. gr. and eq. conductivity at 18°:

	$0·5N$-	N-	$2N$-	$3N$-	$4N$-	$5N$-	$6N$-	$10N$-
Sp. gr. .	1·03389	1·0672	1·1332	1·1981	1·2618	1·3243	1·3857	1·6215
λ .	66·8	58·9	47·46	37·92	30·30	23·54	17·66	4·66

H. C. Jones and H. P. Bassett discussed the hydration of the ions—*vide supra*—and E. C. Banks and co-workers, the transport numbers. O. F. Tower calculated values for the **manganese dioxide electrode** with soln. of manganous nitrate in

nitric acid of different concentrations, and the results were found to agree with $E = -0.0286 \log (C_{Mn}C_H{}^4/C_{Mn}{}^{\cdot}C_H{}^{\cdot4})$, where C_{Mn} refers to the conc. of the manganous ions in two soln., and C_H, the conc. of the $H^{\cdot}$-ions.   L. Bruner found the **hydrolysis** in aq. soln. of manganese nitrate to be too small for measurement.   W. N. Hartley showed that the absorption spectrum of dil. soln. agrees with the assumption that hydrolysis and oxidation produce colloidal $MnO(OH)_2$.   K. Elbs, and E. Frei studied the **electrolysis** of soln. of manganous nitrate, and found that the anodic oxidation is similar to that with sulphate soln. without complications due to the formation of a manganic nitrate—permanganic acid and manganese dioxide being formed instead.   In order to produce permanganic acid, a certain excess of free nitric acid is necessary, and a low concentration of the manganous salt.   Thus, soln. with 0.001, 0.003, and 0.005 mols of $Mn(NO_3)_2$ per litre, required respectively 0.5, 12.0, and 35.0 grms. HNO_3 per 100 c.c. at 16° in order to prevent the formation of manganese dioxide ; and at 60°, soln. with 0.0001, 0.0003, and 0.0006 mols of $Mn(NO_3)_2$ per litre required respectively 5, 23, and 46 grms. of nitric acid per 100 c.c.   G. Jäger and S. Meyer found the **magnetic susceptibility** of aq. soln. of manganous nitrate at 18° to be 82×10^{-6} mass unit, and O. Liebknecht and A. P. Wills gave 86×10^{-6} mass unit.   G. Piaggesi, R. Oppermann, P. Philipp, G. Falckenberg, A. Duperior, and B. Cabrera and co-workers made observations on this subject, and found for soln. with 0.4809 to 0.00732 grm. of anhydrous salt per 1000 grms. of solvent, the mol. susceptibilities respectively 0.0150 to 0.0148, and $4.4 = \chi(T - \Theta)$.

According to W. Ipatéeff and A. Kisseleff, when a soln. of manganous nitrate is treated with **hydrogen** at 300° and over 150 atm. press., the mineral hausmannite, $Mn_3O_4.H_2O$, is formed ; and V. Ipatéeff and B. Muromtzeff found that in quartz tubes Mn_3O_4 is formed, and in gold tubes $Mn_3O_4.H_2O$, at 190° to 240°.   E. H. Westling observed that a soln. of manganous nitrate with lead dioxide furnishes manganese dioxide and lead nitrate.   H. W. Hake found that when the trihydrate is exposed to air, it absorbs moisture equivalent to $Mn(NO_3)_2.16H_2O$.   A. Lührs and K. Kraut found that when the soln. of manganous nitrate in **water** is evaporated on a water-bath, much hydrated manganese dioxide is deposited—particularly in sunlight.   A. Gorgeu obtained the basic salt, **manganous oxynitrate**, $Mn_2O(NO_3)_2$. $3H_2O$, by mixing a boiling 60 per cent. soln. of manganous nitrate with a boiling conc. soln. of sodium carbonate, boiling for two minutes, filtering, and slowly cooling the soln. out of contact with air.   The acicular crystals are dried in darkness ; they turn brown in air when exposed to light ; they are rapidly decomposed by water ; and lose water and nitrogen oxides at 100°.   The basic salt is soluble in a soln. of manganous nitrate.   J. W. Thomas found that hexahydrated manganous nitrate dried in **hydrogen chloride** forms a dark brown liquid containing manganic chloride, water, chlorine, and nitric acid.   E. C. Franklin and C. A. Kraus observed that anhydrous manganous nitrate is insoluble in liquid **ammonia ;** and A. Guntz and F. Martin observed that **manganous enneamminonitrate**, $Mn(NO_3)_2$. $9NH_3$, is formed in white crystals which rapidly turn brown when exposed to air and light ; they are decomposed at 150°, and become incandescent when rapidly heated.   In vacuo the ammine gradually loses ammonia without forming pure nitrate.   The ammine is decomposed by water.   W. Herz studied the equilibrium conditions of soln. of manganous nitrate in the presence of **ammonium salts,** and it is possible that a complex salt is formed.   H. Franzen and O. von Mayer obtained the complex salt **manganous dihydrazinonitrate**, $Mn(NO_3)_2.2N_2H_4$.   J. F. John observed that the hexahydrate is soluble in **alcohol ;** and A. Guntz and F. Martin found that it is soluble in **acetone**, and **benzonitrile**, forming in the latter case the complex $2Mn(NO_3)_2.C_6H_5CN$.   H. Grossmann observed that the anhydrous nitrate forms a complex, $Mn(NO_3)_2.2C_5H_5N$, with **pyridine ;** G. A. Barbieri and F. Calzolari, one, $Mn(NO_3)_2.2C_6H_{12}N_4.10H_2O$, with **hexamethylenetetramine ;** and J. F. Martenson, and H. Traube, one, $Mn(NO_3)_2.2K(SbO)C_4H_4O_6.H_2O$, with **potassium antimonyl tartrates.**

Complex salts of manganous nitrate with the nitrates of the alkalies, alkaline earths, and the magnesium family have not been prepared. C. di Capua's examination of the system $Mn(NO_3)_2-Mg(NO_3)_2-H_2O$ yields no evidence of the formation of a complex salt. A. Mailhe obtained **copper manganous trioxynitrate,** $3CuO.$ $Mn(NO_3)_2.3H_2O$, by boiling copper hydroxide with a conc. soln. of manganous nitrate ; the brown oxide $4CuO.H_2O$ also gave this compound after standing for 3 months with a cold soln. of manganous nitrate. The green powder consists of microscopic needles. The salt becomes brown when exposed to air. A. Werner regarded it as a hexol, $3Cu(OH)_6.Mn(NO_3)_2$, isomorphous with gerhardtite, $Cu(NO_3)_2 \mid 3Cu(OH)_2$. C. di Capua's study of the ternary system $Mg(NO_3)_2-$ $Mn(NO_3)_2-H_2O$, Fig. 114, at 20°, gives no evidence of the formation of a **magnesium manganese nitrate.** A. Mailhe treated a hot soln. of manganous nitrate with mercuric oxide and obtained white rhombic plates of **mercuric manganous oxynitrate** as a *dihydrate*, $Mn(NO_3)_2.HgO.2H_2O$. The salt is decomposed by water, with the separation of mercuric oxide. If yellow or red mercuric oxide be allowed to stand under a conc. soln. of manganous nitrate, white microscopic, hexagonal, bipyramidal prisms of the *trihydrate* are formed. The crystals acquire a black film. If mercuric oxide be dissolved in a warm soln. of manganous nitrate, and the

FIG. 114.—The Ternary System : $Mg(NO_3)_2-Mn(NO_3)_2-H_2O$ at 20°.
FIG. 115.—The Ternary System : $La(NO_3)_3-Mn(NO_3)_2-H_2O$ at 20°.

soln. cooled, white monoclinic plates of the *tetrahydrate* are formed, isomorphous with the corresponding compounds of cobalt and nickel. A. Mailhe also prepared a complex with mercuric cyanide, namely $Mn(NO_3)_2.HgCy_2$.

There is an isomorphous series of complex nitrates of some earths with the nitrates of magnesium, zinc, manganese, iron (ous), cobalt, and nickel. The general formula is $R''_3[R'''(NO_3)_6]_2.24H_2O$. The salts are hygroscopic, and lose a part of their nitric acid at 120°. T. Lange prepared **manganous cerous nitrate,** $Mn_3[Ce(NO_3)_6]_2.24H_2O$, by evaporating a mixed soln. of manganous nitrate and cerous nitrate, and alcohol. The salt was also prepared by H. Zschiesche, and G. Jantsch. A soln. of stoichiometrical proportions of the component salts is evaporated, and the salt is purified by recrystallization. The rose-red crystals are trigonal, and, according to A. Fock, have the axial ratio $a:c=1:1.5775$, and $a=79° 38'$. G. Jantsch gave 2.102 for the sp. gr. at 0°/4°, and 771.6 for the mol. vol. The m.p. is 83.7°. The solubility at 16° in nitric acid of sp. gr. 1.325 at 16°/4° is 0.1103 mol or 178.8 grms. per litre. A. Damour and H. St. C. Deville prepared **manganous lanthanum nitrate,** $Mn_3[La(NO_3)_6]_2.24H_2O$, in a similar way. The crystals are isomorphous with the other members of the series. C. di Capua's study of the system $Mn(NO_3)_2-La(NO_3)_3-H_2O$, Fig. 115, at 20° yielded no evidence of the formation of a complex salt. G. Jantsch found the sp. gr. to be 2.080 at 0°/4°; the mol. vol., 778.6; the m.p., 87.2° ; and the solubility at 16° in nitric acid of sp. gr. 1.325 at 16°/4°, 0.1192 mol or 193.1 grms. per litre at 16°. G. Jantsch

likewise obtained **manganous praseodymium nitrate,** $Mn_3[Pr(NO_3)_6]_2.24H_2O$, in pale yellowish-green crystals of sp. gr. 2·109 at 0°/4°; mol. vol., 769·3; m.p. 81·0°; and the solubility in nitric acid of sp. gr. 1·32 at 16°/4° is 0·1816 mol or 234 grms. per litre at 16°. G. Jantsch prepared **manganous neodymium nitrate,** $Mn_3[Nd(NO_3)_6]_2.24H_2O$, in similar manner. The pale violet-red crystals have a sp. gr. 2·114 at 0°/4°; mol. vol., 771·0; m.p., 77·0°; solubility at 16° in nitric acid of sp. gr. 1·325 at 16°/4°, 0·1816 mol or 296·0 grms. per litre at 16°. G. Jantsch similarly obtained **manganous samarium nitrate,** $Mn_3[Sa(NO_3)_6]_2.24H_2O$, in reddish-yellow crystals of sp. gr. 2·188 at 0°/4°; mol. vol. 750·3; m.p., 70·2°; and solubility in nitric acid of sp. gr. 1·325 at 16°/4°, 0·3047 mol or 500·4 grms. per litre at 16°. The great solubility of **manganous gadolinium nitrate** seemed to prevent its crystallization; the **manganous yttrium nitrates** have not been prepared.

According to M. Holzmann, when hot or cold, conc. or dil. soln. of ceric and manganous nitrates are mixed, hydrated manganese dioxide is precipitated, and the ceric salt is reduced to the cerous state of oxidation. R. J. Meyer and R. Jacoby found that if a filtered soln. of 11 parts of manganous carbonate in nitric acid is mixed with a little water, and allowed to run slowly, with constant stirring, into a well-cooled soln. of 20 parts of ceric hydroxide in nitric acid of sp. gr. 1·4, and allowed to stand, some hydrated manganese dioxide is formed, and at the same time aggregates of dark red, tabular crystals of **manganous ceric nitrate,** $MnCe(NO_3)_6.8H_2O$, are formed. The crystals are very sensitive to moist air, and decompose with the separation of hydrated manganese dioxide. They dissolve in conc. nitric acid. A. Fock said that the trigonal crystals have the axial ratio $a:c=1:1.5775$, and $\alpha=79°38'$; the (111)-cleavage is nearly perfect; and the optical character is negative. R. J. Meyer and R. Jacoby observed that a mixed soln. of thorium and manganous nitrates furnishes colourless plates of **manganous thorium nitrate,** $MnTh(NO_3)_6.8H_2O$, mixed with some thorium nitrate.

G. Urbain and H. Lacombe prepared with bismuth nitrate a series of double salts with the nitrates of magnesium, zinc, manganese, cobalt, and nickel, having the general formula $3R(NO_3)_2.2Bi(NO_3)_3.24H_2O$, or $R_3[Bi(NO_3)_6]_2.24H_2O$. They are isomorphous with the corresponding complex nitrates of the rare earths. They are efflorescent in dry air, and deliquescent in moist air. They are prepared in a similar manner, and are all decomposed by water. The most unstable salt of the series is **manganous bismuth nitrate,** $Mn_3[Bi(NO_3)_6]_2.24H_2O$. It does not exist in contact with the solid phase of either constituent. The salt is pale red; its sp. gr. is 2·42 at 16°; it melts without decomposition at 43° to 44°. G. Jantsch found that its solubility in nitric acid of sp. gr. 1·325 at 16°/4° is 0·3742 mol or 657·7 grms. per litre at 16°.

C. T. Barfoed [2] was unable to prepare **manganic nitrate,** $Mn(NO_3)_3.nH_2O$, by the action of nitric acid on manganic hydroxide; by the action of barium nitrate on manganic sulphate; or by the action of silver nitrate on manganic chloride. M. Sem considers that he obtained manganic nitrate in soln. by the electrolytic oxidation of a soln. of manganous nitrate in fuming nitric acid, but he could not isolate the compound as such or in the form of potassium manganic nitrate. J. Meyer, however, said that the product is colloidal manganese dioxide.

§ 26. Manganous Phosphates

H. Struve [1] prepared **manganous orthophosphate,** $Mn_3(PO_4)_2$, by passing hydrogen for a long time over white-hot manganous pyrophosphate : $3Mn_2P_2O_7 = 2Mn_3(PO_4)_2 + P_2O_5$—some phosphorus, phosphine, and manganese phosphide are also formed. The anhydrous salt is produced by heating a hydrate to redness. Several hydrates have been reported. If a manganous salt soln. be treated with an excess of sodium hydrophosphate, the analyses of W. Heintz, and of E. Erlenmeyer and O. Heinrich show that the white amorphous precipitate is a *heptahydrate*, $Mn_3(PO_4)_2.7H_2O$. If manganous hydrophosphate be treated with cold water so long as it acquires an acidic reaction, acicular crystals are obtained which, according to E. Erlenmeyer and O. Heinrich, approximate to the *pentahydrate*, $Mn_3(PO_4)_2.5H_2O$, although the analytical data for the air-dried product ranges

from $4\frac{1}{2}$ to $5\frac{1}{2}$ H_2O. F. Grossmann obtained the pentahydrate by the action of water on ammonium manganous phosphate. The salt was also prepared in a crystalline state by F. Ephraim and C. Rossetti. According to E. Erlenmeyer and O. Heinrich, if the hepta- or pentahydrate be dried over conc. sulphuric acid, the *hemiheptahydrate*, $Mn_3(PO_4)_2.3\frac{1}{2}H_2O$, is formed; and if heated to 100°, the *trihydrate*, $Mn_3(PO_4)_2.3H_2O$, is produced. H. J. Debray also obtained crystals of the trihydrate by heating manganous hydrophosphate with water at 100° to 140°; and also by boiling manganous carbonate with an excess of phosphoric acid. H. J. Debray also prepared the *monohydrate*, $Mn_3(PO_4)_2.H_2O$, by heating the trihydrate with water in a sealed tube at 250°. H. T. S. Britton titrated electrometrically $0.02M\text{-}MnCl_2$ with $0.1N\text{-}Na_3PO_4$ at 20° and obtained the curve shown in Fig. 116. The phosphate began to separate when $p_H=5.76$, and it may be added that the hydroxide separation occurs when $p_H=8.43$.

FIG. 116.—Electrometric Titration of Solutions of Manganous Chloride with Sodium Phosphate.

F. Müllbauer obtained in Hagendorf, Bavaria, pale rose or flesh red rosettes of a *pentahydrate*, $Mn_3(PO_4)_2.5H_2O$; or rather $(Fe,Mn,Mg)_3(PO_4)_2.5H_2O$; he called the mineral **wenzelite**—after H. Wenzel. The monoclinic prisms have the axial ratios: $a:b:c=2.3239:1:2.8513$. The biaxial crystals are optically negative. G. J. Brush and E. S. Dana found a granular, massive, or crystalline mineral near Redding, Connecticut, and they called it **reddingite.** Its colour is pinkish-white, pale rose-pink, or yellowish-white. Its composition corresponds with the trihydrate, $Mn_3(PO_4)_2.3H_2O$. A little iron may replace the manganese; and H. Berman and F. A. Gonyer gave $3(Mn,Fe)O.P_2O_5.3H_2O$. According to G. J. Brush and E. S. Dana, the crystals of reddingite are rhombic with the axial ratios $a:b:c=0.8678:1:0.9486$; the habit is octahedral, and the crystals often occur in parallel groupings. There is a distinct cleavage. The crystals of reddingite appear as if they were isomorphous with scorodite, $Fe_2(AsO_4)_2.4H_2O$, and strengite, $Fe_2(PO_4)_2.4H_2O$, although their chemical nature is different. E. H. Kraus and co-workers gave $a:b:c=0.5271:1:0.4574$. A. des Cloizeaux found that the crystals of H. J. Debray's preparation of the trihydrate resemble **hureaulite,** $H_2R''_5(PO_4)_4.4H_2O$. G. J. Brush and E. S. Dana gave 3.102 for the sp. gr. of reddingite, and 3.0 to 3.5 for the hardness. H. Berman and F. A. Gonyer gave 3.136 for the sp. gr. E. H. Kraus and co-workers gave for the indices of refraction $a=1.651$, $\beta=1.656$, and $\gamma=1.683$; and H. Berman and F. A. Gonyer, $a=1.655$, $\beta=1.662$, and $\gamma=1.683$, and they said that the optical character is positive, and the optic axial angle $2V=65°$. According to E. Erlenmeyer and O. Heinrich, the heptahydrate loses about $3\frac{1}{2}$ mols. of water over conc. sulphuric acid; and about 3 mols. at 100°; W. Heintz observed a loss of 15.90 per cent. of water between 110° and 120°. According to M. Berthelot, the heat of formation of the amorphous or colloidal orthophosphate is $(2P,4O_2,3Mn)=737.5$ Cals.; and $2H_3PO_{4aq.}+3Mn(OH)_2=Mn_3(PO_4)_2+Aq.+45.3$ Cals. K. Elbs, and E. Frei found that when a soln. of manganous carbonate in phosphoric acid is electrolyzed, manganese dioxide is formed, together with an amethyst-red soln. of manganic phosphate. G. Grube and M. Staesche found the oxidation potential of a soln. of a manganic salt in phosphoric acid involves the two changes: $2Mn'''\rightleftharpoons Mn''+Mn''''$ followed by $4Mn''''\rightleftharpoons 3Mn'''+Mn''''$. The equilibrium is affected by the conc. of the phosphoric acid and very little by the conc. of the manganese. For 0.02 gram-atom Mn in a litre of $37.8N\text{-}H_3PO_4$ at 12°, with $Mn'':Mn'''=1:1$, the oxidation potential for $Mn''\rightarrow Mn'''$ is

1·221 volts ; and for $Mn^{...} \rightarrow Mn^{....}$, 1·526 volts. The equilibrium constant K, and the percentage decomposition of manganic phosphate for $2Mn^{...} \rightleftharpoons Mn^{..} + Mn^{....}$, a, are for a soln. with 0·02 gram-atom per litre at 12° :

N-H_3PO_4	45·0	42·5	40·0	37·5	35·0	32·5	30·0
K	0·048	0·0076	$0·0_316$	$0·0_530$	$0·0_528$	$0·0_420$	$0·0_317$
a	30·0	15·0	2·4	0·35	0·33	0·89	2·6 per cent.

There is thus a maximum decomposition of the tervalent manganese phosphate in highly conc. acid, and a minimum in $30N$- to $35N$-H_3PO_4, and thereafter the decomposition increases slowly as the acidity increases. With the quadrivalent manganese phosphate equilibrium : $4Mn^{....} \rightleftharpoons 3Mn^{...} + Mn^{.....}$, for a soln. with 0·01 gram-atom Mn in a litre of $40·5N$-H_3PO_4 at 12°, with $Mn^{....} : Mn^{.....} = 1 : 1$, the oxidation potential for $Mn^{....} \rightarrow Mn^{.....}$ is 1·639 volts. The equilibrium constant, K, and the percentage decomposition of the quadrivalent manganese diphosphate, a, are for a soln. with 0·01 gram-atom Mn per litre at 12° :

N-H_3PO_4	45·0	40·0	35·0	30·0	25·0	22·5	20
K	$0·0_{22}21$	$0·0_{16}41$	$0·0_526$	$0·0_596$	$0·0_521$	$0·0_417$	$0·0_317$
a	0·0038	0·014	3·9	8·9	7·9	10	16 per cent.

As the acidity diminishes, the equilibrium shifts rapidly and continuously from left to right, so that the salt can be prepared only in highly acidic soln. Quadrivalent manganese diphosphate is a better oxidizing agent than permanganic acid, and a better reducing agent than tervalent manganic phosphate. F. Weckbach studied the electrolytic oxidation of soln. of manganous phosphate in phosphoric acid ; and J. Chloupek, the potential of a platinum electrode in soln. of phosphoric acids and manganous oxide.

J. J. Berzelius found that water dissolves very little of the heptahydrate, and L. Joulin said that the salt is not decomposed by water, but F. Grossmann found that the pentahydrate suffers hydrolysis when it is shaken· with water at 25° ; a limiting value was not obtained ; only phosphoric acid. not manganous ions, pass into soln., so that either manganous hydroxide or a basic salt is formed as a result of the hydrolysis. F. Fichter and E. Brunner found that manganous phosphate is oxidized by fluorine to the manganic salt. C. D. Braun observed that when the heptahydrate is warmed with hydrochloric acid, a brown soln. is formed which deposits a dark brown crystalline precipitate. W. Heintz said that the phosphate is readily soluble in mineral acids, and in acetic acid. B. W. Gerland found that sulphurous acid readily dissolves the phosphate. W. Heintz observed that aq. ammonia converts it into ammonium manganous phosphate ; and J. J. Berzelius said that a boiling soln. of potassium hydroxide extracts all the phosphoric acid ; and a soln. of ammonium carbonate dissolves the phosphate, but it is re-precipitated when the soln. is boiled. According to R. H. Brett, a soln. of ammonium chloride or nitrate dissolves some phosphate ; and G. C. Wittstein observed a similar result with a soln. of ammonium sulphate or succinate. W. Heintz said that the salt is insoluble in alcohol. L. Joulin said that the heptahydrate is not decomposed by a soln. of sodium dihydrophosphate, but it is decomposed by a soln. of the hydrophosphate, forming manganous hydroxide, or, if exposed to air, hydrated manganic oxide. C. D. Braun found that lead dioxide colours the phosphate violet-grey. W. Muthmann and H. Heramhof tried the phosphate as a colouring agent for porcelain painting. W. Knaust studied the coagulation of colloidal soln. of manganese oxide peptized with phosphoric acid.

H. St. C. Deville and H. Caron heated a mixture of ammonium phosphate and an excess of manganous chloride to a bright red-heat, and extracted the cold mass with water. There remain crystals of **manganese chlorophosphate,** $Mn_3(PO_4)_2$. $MnCl_2$, or *manganese wagnerite.* If 2 parts of manganous fluoride and 5 parts of ammonium phosphate be fused with an excess of manganous chloride, and the cold mass extracted with water, there remain crystals of **manganous chlorotriorthophosphate,** $3Mn_3(PO_4)_2.MnCl_2$, or *manganese apatite.* A. Ditte melted manganous

bromide with an excess of ammonium dihydrophosphate, and extracted the cold mass with hot water. Needle-like prisms of **manganous bromotriorthophosphate,** $3Mn_3(PO_4)_2.MnBr_2$, or *manganese bromoapatite* remained.

According to C. H. D. Bödeker, and E. Erlenmeyer and O. Heinrich, if a soln. of manganous sulphate be treated with a slight excess of sodium hydrophosphate, the soln. and precipitate be divided into two equal parts, and one part treated with enough nitric or hydrochloric acid just to dissolve the precipitate, and then mixed with the other part, and allowed to stand for 2 or 3 days, pale red, almost colourless, crystals of **manganous hydrophosphate,** $MnHPO_4.3H_2O$, are formed. W. Heintz obtained the same salt by adding sodium hydrophosphate to a soln. of manganous sulphate, acidulated with acetic acid until a permanent precipitate is formed. All the manganese must not be precipitated; if hydrochloric or nitric acid be employed in place of acetic acid, the precipitation is slower. After the precipitate has stood for a while it becomes granular and crystalline. This salt is also produced as a residue when an excess of pentahydrated normal phosphate is boiled with phosphoric acid. The washed precipitate becomes crystalline on standing. M. Amadori investigated the ternary system $MnO-P_2O_5-H_2O$ at 25°, and the results are summarized in Fig. 117, which shows the range of stability of

FIG. 117.—Equilibrium Conditions in the System : $MnO-P_2O_5-H_2O$ at 25°.

FIG. 118.—Equilibrium Conditions in the System : $Mn_3(PO_4)_2-H_3PO_4-H_2O$ at 25°.

the trihydrate. The results of G. Grube and M. Staesche in the system $Mn_3(PO_4)_2-H_3PO_4-H_2O$ at 25° are summarized in Fig. 118. The solubility curves of the solid phases are ab, for $Mn_3(PO_4)_2$; bc, for $MnHPO_4$; cd, for $Mn(H_2PO_4)_2.3H_2O$; and de, for phosphoric acid, probably $2H_3PO_4.H_2O$. The curve for 55° is dotted in Fig. 118. E. Erlenmeyer and O. Heinrich found that when the dihydrophosphate is allowed to deliquesce in moist air, or digested with one and a half vols. of water, the hydrophosphate is formed ; likewise also when the dihydrophosphate is boiled with alcohol. H. J. Debray obtained the hydrophosphate by adding alcohol to a soln. of manganous carbonate in phosphoric acid until a turbidity appears. C. H. D. Bödeker said that the crystals are tabular, right rhombic prisms, having the acute prismatic edges generally replaced by planes, so that the crystals look like hexagonal plates. C. von Haushofer said that the tabular or octahedral crystals are rhombic, with the axial ratios $a:b:c=0.9445:1:0.9260$. The crystals lose no water in dry air over calcium chloride ; at 110°, C. H. D. Bödeker found that they lose 23·27 per cent. of water; at 110° to 120°, W. Heintz found that 22·47 per cent. is lost ; and E. Erlenmeyer and O. Heinrich, at 100°, 22·24 per cent. This water is taken up again when the crystals are exposed to air. W. Heintz found that three mols. of water are lost at 200°, and at a red-heat pyrophosphate is formed. The salt is slowly hydrolyzed by cold water, and with boiling water a soluble acid salt and an insoluble basic salt are formed. W. Heintz found that the salt is readily soluble in the strong mineral acids, but it dissolves with difficulty in acetic

acid, and it is insoluble in alcohol; B. W. Gerland observed that it is readily soluble in sulphurous acid; and R. H. Brett, that when dissolved in a soln. of ammonium chloride it gives no precipitate with hydrogen sulphide. F. Fichter and E. Brunner found that when fluorine acts on a soln. of the phosphate, oxidation takes place to an extent not exceeding 66 per cent. The incomplete oxidation is again attributed to the formation of hydrogen dioxide. As permonophosphoric acid is formed by the action of fluorine on orthophosphoric acid, this oxidation may be explained by the theory that the oxidizing agent is a peroxide or peracid derived from the anion, such as sulphur tetroxide in the case of sulphates. The mineral **seamanite**—named after A. F. Seaman—is a hydrated **manganous borophosphate**, $3MnO.(B_2O_3.P_2O_5).3H_2O$, or $3MnO.B_2O_3.3H_2O$ associated with $3MnO.$ $P_2O_5.3H_2O$, and it is related with reddingite. Both minerals are rhombic. E. H. Kraus gave for the axial ratios $a:b:c=0.5195:1:0.4508$; 3.128 for the sp. gr.; 4.0 for the hardness; and for the indices of refraction, $\alpha=1.640, \beta=1.663$, and $\gamma=1.665$—*vide supra*, reddingite.

W. Heintz prepared **manganous dihydrophosphate**, $Mn(H_2PO_4)_2.2H_2O$, by strongly heating a mixture of manganic oxide and phosphoric acid; and by allowing a soln. of normal manganous phosphate in phosphoric acid to stand for crystallization. The equilibrium conditions found by M. Amadori are indicated in Fig. 117, and by G. Grube and M. Staesche, in Fig. 118. E. Erlenmeyer and O. Heinrich obtained this salt by allowing a soln. of manganous sulphide in an excess of phosphoric acid to evaporate in a warm place. In three weeks the crystalline crust is pressed between bibulous paper, or washed with water and ether free from alcohol. A. Joly found that in the formation of the phosphate the gelatinous hydrophosphate is first precipitated, and that this gradually passes into the crystalline dihydrophosphate. According to E. Erlenmeyer and O. Heinrich, the four-sided, prismatic crystals of the dihydrophosphate are not changed by exposure to dry air, but they deliquesce in moist air, forming the hydrophosphate. The salt loses 12.61 per cent. of water at 100°, or, according to W. Heintz, 13.15 per cent. at 110°–120°, and the remaining water is expelled at a red-heat. The salt on charcoal readily fuses in the oxidizing flame of the blowpipe, giving off phosphoric acid and phosphorus in inflammable bubbles. The salt is easily soluble in water; and E. Erlenmeyer and O. Heinrich said that if the salt contains a trace of free phosphoric acid, it readily dissolves in a little water; and, added H. J. Debray, alcohol precipitates the hydrophosphate from the aq. soln. According to W. Heintz, the salt is resolved by boiling alcohol into phosphoric acid and the hydrophosphate. According to G. Viard, if 10, 20, and 100 grms. of manganous dihydrophosphate, $Mn(H_2PO_4)_2.$ $2H_2O$, per 100 grms. of water at 0° be allowed to stand for many days, the mol. ratios $P_2O_5:MnO$ in the soln. are respectively 1.06, 1.14, and 1.19; and there are 19.75, 33.39, and 97.42 grms. respectively of MnO per litre in the soln., and respectively 41.90, 76.04, and 232.05 grms. per litre of P_2O_5. The composition of the soln. thus deviates more and more from that of the original salt the greater is the proportion of dihydrophosphate employed, and it is possible to arrange that a gram of salt dissolves in 100 grms. of water without decomposition. Working at 100°, with increasing proportions of dihydrophosphate, the mol. ratio $P_2O_5:MnO$ in the soln. increases to a maximum and then slowly decreases. If less than 20 grms. of dihydrophosphate per 100 grms. of water be used, the decomposition proceeds like that of barium or calcium phosphate at 0° or 100°, and like that of manganous dihydrophosphate at 0°. If G denotes the number of grams of $Mn(H_2PO_4)_2.2H_2O$ in 100 grms. of water; $P_2O_5:MnO$, the ratio in soln.; MnO, grams in soln.; and P_2O_5, grams in soln.:

G	.	0.5	1	5	10	20	30	50	200	400
$P_2O_5:MnO$		1.24	1.38	1.75	1.85	1.88	1.83	1.75	1.55	1.52
P_2O_5	.	1.926	1.56	5.43	9.87	18.00	26.39	41.53	106.04	133.77
MnO	.	2.29	4.30	19.06	36.55	67.80	96.75	145.27	330.12	405.95

G. Viard said that the product of the action at 100° is always **manganous dihydro-**

tetraorthophosphate, $Mn_3(PO_4)_2.2MnHPO_4.4H_2O$—M. Amadori gave $Mn_5H_2(PO_4)_5$. $5H_2O$, which was prepared by E. Erlenmeyer and O. Heinrich by boiling manganous hydrophosphate with water until it no longer imparts an acidic reaction to the liquid.   The rose-coloured, microscopic prisms are monoclinic, having, according to C. von Haushofer, the axial ratios $a : b : c = 1.9927 : 1 : 1.7122$, and $\beta = 97° 34'$. They lose water above 150° and do not fuse at a red-heat.   A. de Schulten obtained this salt in the form of the mineral hureaulite by adding ammonia, drop by drop, to a soln. of phosphoric acid of sp. gr. 1.1, sat. with manganous carbonate.   The crystals have a sp. gr. 3.175 at 15°.   M. Amadori also prepared **manganous hepta-hydrotriorthophosphate,** $Mn(H_2PO_4)_2.H_3PO_4$, under the conditions illustrated by Fig. 117.   F. Ephraim and C. Rossetti prepared the acid salt $5MnO.2P_2O_5.8H_2O$ in a crystalline state.

F. Alluaud, and A. des Cloizeaux and A. Damour described a mineral from Limoges, Huréaux commune, and it was called **hureaulite.**   The analyses of these and samples from other localities reported by P. A. Dufrénoy, A. des Cloizeaux and A. Damour, and G. J. Brush and E. S. Dana, correspond with the formula $5MnO$. $2P_2O_5.5H_2O$, or $H_2Mn_5(PO_4)_4.4H_2O$, the *pentahydrate* of **manganous dihydrotetra-orthophosphate.**   The colour of hureaulite is orange-red, brownish-orange, rose-violet, pale rose, grey, or nearly colourless.   The streak is nearly white.   The mineral may occur in compact, scaly, or imperfectly fibrous masses, or in isolated or grouped crystals—the groupings may be mammillary or fascicled.   The short prismatic crystals are sometimes tabular, and, according to G. J. Brush and E. S. Dana, they are monoclinic, with the axial ratios $a : b : c = 1.9192 : 1 : 0.5245$, and $\beta = 84° 1'$.   The (100)- and (110)-faces may be striated.   A. des Cloizeaux and A. Damour found the sp. gr. of the yellow crystals to be 3.185, and of the red crystals 3.198 ; G. J. Brush and E. S. Dana gave 3.149 for the sp. gr.   The hardness is 5. A. des Cloizeaux and A. Damour found that the optic axial angle for yellow light is $2H = 86° 22'$; and as the temp. rises 100°, the angle changes 6° 34'.   W. T. Schaller described a mineral from Pala, California, which he called **palaite,** and its analysis corresponds with the *tetrahydrate* of manganous dihydrotetraorthophosphate, $5MnO.2P_2O_5.4H_2O$, or $H_2Mn_5(PO_4)_4.3H_2O$.   Its sp. gr. is 3.14 to 3.20 ; and its mean refractive index is 1.655.

F. J. Otto prepared **ammonium manganous phosphate,** $(NH_4)MnPO_4.H_2O$, by boiling a mixture of a soln. of manganous chloride, hydrochloric acid, and sodium hydrophosphate or phosphoric acid, saturating the liquid with ammonia, and immediately corking the flask.   The white hydrated manganous phosphate first precipitated changes immediately into pearly scales of the complex salt, which are then collected on a filter and washed with water.   If air be not excluded, manganic oxide is formed, and it imparts a reddish tinge to the salt ; but when once formed the salt is not altered by air or by water containing air.   W. Heintz prepared it by dropping an excess of a soln. of sodium hydrophosphate into a cold, feebly ammoniacal soln. of a manganous salt and ammonium chloride.   O. W. Gibbs mixed a soln. of a manganous salt with an excess of sodium hydrophosphate, dissolved in an excess of hydrochloric acid, heated the mixture to its b.p., saturated it with ammonia, and boiled it for 15 mins.   C. D. Braun, and F. Grossmann used an analogous process.   According to F. J. Otto, and P. Nuka, the salt forms white pearly scales, which when heated give off ammonia and water, forming manganous pyrophosphate. W. Heintz said that at 110° to 120° the salt loses only hygroscopic water. F. J. Otto said that it does not dissolve in cold or boiling water, but C. R. Fresenius found that 100 parts of cold water dissolve 0.00304 part of the salt ; and 100 parts of boiling water, 0.00497 part.   F. Grossmann observed that the salt is decomposed by water : $3(NH_4)MnPO_4 + 8H_2O = NH_3 + (NH_4)_2HPO_4 + Mn_3(PO_4)_2.8H_2O$.   A litre of water can transform 0.3032 grm. of the salt.   The proportion transformed is reduced in the presence of sodium or ammonium hydrophosphate, ammonium chloride, or manganous sulphate, all of which furnish ions corresponding with those given by the substances on the right side of the above equation.   The decom-

position of the salt by 0·005N-phosphoric acid is attributed to the decrease in the phosphate ions by the acid. Acetic and carbonic acid first transform the complex salt into normal manganous phosphate, before forming the respective manganous salts. F. J. Otto found that the salt is easily soluble in acids, and when ammonia is added to the soln., manganous phosphate is precipitated, but this immediately forms ammonium manganous phosphate. O. W. Gibbs said that the salt is not soluble in aq. ammonia or soln. of ammonium salts ; but C. R. Fresenius observed that 100 parts of a 1·4 per cent. soln. of ammonium chloride dissolve 0·00562 part, and since ammonia forms some manganous hydroxide, an excess of ammonia is to be avoided when manganese is precipitated as ammonium manganous phosphate in analytical work. F. J. Otto found that with a conc. soln. of potassium hydroxide, ammonia is evolved, but the salt is not decomposed by aq. ammonia, or a soln. of potassium carbonate. P. Wenger found the composition of the dried salt to correspond with the *heptahydrate*, $(NH_4)MnPO_4.7H_2O$. The solubility in water below 60° is too small for measurement by gravimetric analysis ; but, expressing the solubility as S parts of $NH_4MnPO_4.7H_2O$ in 100 parts of solvent, with a soln. of 4 per cent. ammonia and 5 per cent. ammonium chloride, $S=0.0158$ at 20° and 0·0245 at 60°, while with a soln. of 4 per cent. ammonia and 10 per cent. ammonium chloride, $S=0.0375$ at 20° and 0·0543 at 60° ; and with the solvents water, 5 per cent. NH_4NO_3, 5 per cent. NH_4Cl, and N-HCl :

G. J. Brush and E. S. Dana obtained from Branchville, Connecticut, a mineral which was named **lithiophilite**—from lithium and $\phi\iota\lambda o\varsigma$, a friend. Its analysis, reported by J. F. Schairer, G. J. Brush and E. S. Dana, E. S. Simpson, and S. L. Penfield, corresponds with **lithium manganous phosphate**, $LiMnPO_4$, where Mn represents bivalent manganese and iron ranging from 1 : 0·5 to 1 : 0, so that the colour varies with the proportion of iron from salmon-pink to clove-brown lithiophilite, with very little iron, to bluish-grey triphylite containing very little manganese. The colour of lithiophilite may be greenish-grey, salmon-pink, honey-yellow, yellowish-brown, and light clove-brown. It may be nearly black on the surface. The streak is colourless to greyish-white. The pleochroism is $a=$deep pink, $b=$faint pink, and $c=$pale greenish-yellow. The rhombic crystals are isomorphous with those of triphylite—*vide infra*. The optical character is negative—H. Berman and F. A. Gonyer said positive. For the index of refraction by S. L. Penfield and J. H. Pratt, *vide* triphylite. E. Sommerfeldt gave for the optic axial angle, $2V=56° 4'$, and, for Na-light, the change with temp. from $-15°$ to 19° exceeds 17° 34'. H. Berman and F. A. Gonyer gave $2V=60°$. The sp. gr. observed by G. J. Brush and E. S. Dana ranges from 3·424 to 3·432, and by S. L. Penfield, from 3·398 to 3·504. H. Berman and F. A. Gonyer gave 3·481. The hardness is 4·0 to 4·5. H. Berman and F. A. Gonyer gave for the indices of refraction $a=1.675$, $\beta=1.679$, and $\gamma=1.688$. The transformations in nature were discussed by G. J. Brush and E. S. Dana, and by F. P. Dewey. J. N. von Fuchs described a mineral from Bodenmais, Bavaria, which he named **triphylite** or rather *triphylin*—from $\tau\rho\iota\varsigma$, threefold, and $\phi\upsilon\lambda\acute{\eta}$, family, in allusion to its containing three phosphates. J. J. Berzelius called a sample from Finland, *tetraphylin*; and N. G. Nordenskjöld, *perowskyn*. Analyses were reported by J. N. von Fuchs, E. P. Henderson, F. Oesten, G. C. Wittstein, C. F. Rammelsberg, S. L. Penfield, A. Lacroix, and W. Baer. The analyses agree with the formula $Li(Mn,Fe)PO_4$. As just indicated, there is a range of isomorphous lithiophilites and triphylites with almost $LiMnPO_4$ at one end of the series and $LiFePO_4$ at the other end. The colour is greenish-grey or bluish-grey, passing into the colours of lithiophilite. Triphylite usually occurs in cleavable or compact masses ; the crystals are rare. The faces are uneven. G. Tschermak

found the axial ratios of the rhombic crystals to be $a : b : c = 0.4348 : 1 : 0.5265$. The (001)-cleavage is perfect ; the (010)-cleavage is distinct ; and the (110)-cleavage is interrupted.   The optical character is positive ; and the optic axial angle $2H_a$ is $74° 45'$ for red-light, and $2H_a = 79° 30'$ for blue-light.   For $2V$, *vide infra.* J. D. Dana also examined the crystals.   F. Oesten gave for the sp. gr., 3.545 to 3.561 ; and S. L. Penfield, 3.482 to 3.549.   The hardness is between 4 and 5. S. L. Penfield and J. H. Pratt found for the indices of refraction of samples with different proportions of iron, for Na-light :

FeO .	.	.	4.24	9.42	13.63	26.58	35.05 per cent.

M. Berthelot found that in precipitating a soln. of manganous chloride with sodium phosphate, the colloidal precipitate rapidly becomes crystalline, forming **sodium manganous phosphate,** $NaMnPO_4$, and the heat of the reaction is 7·5 Cals. G. J. Brush and E. S. Dana described a mineral **natrophilite** consisting of sodium manganous phosphate, $NaMnPO_4$.   It occurs at Branchville, Connecticut.   Its colour is deep wine-yellow.   It usually occurs in cleavable masses, and also in rhombic crystals isomorphous with lithiophilite.   Its (001)-cleavage is perfect, the (010)-cleavage is distinct, and the (110)-cleavage is interrupted.   The optical character is positive ; the sp. gr. is 3·41 ; and the hardness 4·5 to 5·0.   L. Ouvrard melted manganous oxide with sodium pyrophosphate, sodium phosphate, or metaphosphate, particularly in the presence of sodium chloride, and obtained rhombic prisms of sodium manganous phosphate, $NaMnPO_4$, isomorphous with the zinc and cadmium salts.   Its sp. gr. is 3·1 at 20°.   If rather less sodium pyrophosphate is employed dendrites of **sodium manganous diorthophosphate,** $Na_4Mn(PO_4)_2$, are formed. The sp. gr. is 2·7 at 20°.   E. Cohen obtained crystals of $2Na_2HPO_4.Mn_3(PO_4)_2.7H_2O$, as a by-product in the preparation of sodium hydrophosphate.   L. Ouvrard obtained **potassium manganous phosphate,** $KMnPO_4$, by melting an excess of manganous oxide with potassium metaphosphate, or with potassium chloride and sodium phosphate or pyrophosphate ; and H. Grandeau, by melting at a high temp. a mixture of manganous hydrophosphate and an excess of potassium sulphate. L. Ouvrard found that the rose-pink crystals are probably rhombic, and have a sp. gr. of 3·2 at 20°.   G. Grube and M. Staesche regarded manganous dihydrophosphate as a manganodiphosphoric acid, $H_4[Mn(PO_4)_2].3H_2O$.   The colourless crystals in contact with water gradually form the normal phosphate.   Two salts were prepared in stable, colourless crystals, namely **potassium manganous trihydrodiphosphate,** $K_3H[Mn(PO_4)_2].5H_2O$; and **sodium manganous dihydrodiphosphate,** $Na_2H_2[Mn(PO_4)_2].4H_2O$.

G. J. Brush and E. S. Dana found a **calcium manganous phosphate,** $Ca_2Mn(PO_4)_2.$ $2H_2O$, at Branchville, Fairfield Co., Connecticut, and they called it **fairfieldite.** H. Berman and F. A. Gonyer represented the composition by $(Mn,Fe)O.2CaO.$ $P_2O_5.2H_2O$.   According to G. J. Brush and E. S. Dana, the colour of fairfieldite is white, greenish-white, or pale straw-yellow ; its streak is white.   It occurs in foliated or lamellar crystalline aggregates, and in radiating or foliated masses.   It also furnishes prismatic crystals probably belonging to the triclinic system, with the axial ratios $a : b : c = 0.2797 : 1 : 0.1976$, and $a = 102° 8\frac{5}{8}'$, $\beta = 94° 33\frac{1}{3}'$, and $\gamma = 77° 19\frac{1}{6}'$. The (010)-cleavage is perfect, and the (100)-cleavage is distinct.   The sp. gr. is 3·07 to 3·15, and the hardness 3·5.   H. Berman and F. A. Gonyer gave 3·016 for the sp. gr., and for the indices of refraction, $a = 1.640$, $\beta = 1.650$, and $\gamma = 1.660$; the optical character is positive ; and the optical axial angle $2V = 86°$.   F. Sandberger obtained a variety from Zwiesel, Bavaria, which he called *leucomanganite.*   S. L. Penfield obtained **calcium manganous phosphate,** $(Ca,Mn,Fe)_3(PO_4)_2$, from the neighbourhood of Grafton, New Hampshire, and he called it **graftonite.**   The mineral is also associated with ferrous oxide.   Its colour when fresh is salmon-pink, and it occurs

in monoclinic crystals with the axial ratios $a : b : c = 0.886 : 1 : 0.582$, and $\beta = 66°$. The sp. gr. is 3·672, and the hardness 5.

A hydrated **manganous aluminium phosphate** was obtained by G. J. Brush and E. S. Dana, from Branchville, Connecticut; and K. K. Landes reported it from several places in Maine. It was named **eosphorite**—$\epsilon\omega\sigma\phi\acuteo\rho o\varsigma$, dawn bearing, in allusion to the pink colour. It occurs in rose-pink, yellowish, or colourless crystals of the composition $2AlPO_4.2(Fe,Mn)(OH)_2 + 2H_2O$. The analysis reported by C. Palache and E. V. Shannon agrees with $2MnO.Al_2O_3.P_2O_5.4H_2O$. It also occurs compact. The rhombic crystals have the axial ratios $a : b : c = 0.77680 : 1 : 0.51501$; the (100)-cleavage is nearly perfect. The habit is prismatic, and the faces in the zone (100) : (010) have vertical striations. The sp. gr. is 3·11 to 3·145, and the hardness 5. The mineral is feebly pleochroic. α is colourless, β light yellow, and γ brown. The optical character is negative; the optic axial angle $2V = 50°$, and $2H = 54° 30'$. The indices of refraction $\alpha = 1.638$, $\beta = 1.660$, and $\gamma = 1.667$. E. S. Larsen gave for the indices of refraction $\alpha = 1.631$ to 1·633, $\beta = 1.660$ to 1·678, and $\gamma = 1.664$ to 1·684. G. J. Brush and E. S. Dana obtained a mineral from Branchville, Connecticut, which they called **fillowite**—after A. N. Fillow. Its analysis corresponds with **sodium calcium manganous ferrous phosphate**, $(Ca,Mn,Fe,Na_2)_3(PO_4)_2.H_2O$, where the ratios Mn : Fe+Ca : Na$_2$ $= 6 : 2 : 1$. The waxy yellow or reddish- or yellowish-brown mineral occurs in granular crystalline masses; the habit of the crystals is pseudorhombohedral. The monoclinic crystals have the axial ratios $a : b : c = 1.7303 : 1 : 1.4190$, and $\beta = 89° 50\frac{2}{3}'$. The (001)-cleavage is very distinct. The sp. gr. is 3·43, and the hardness 4·5. The same locality furnished G. J. Brush and E. S. Dana with a mineral **dickinsonite**—after W. Dickinson—whose analysis corresponds with sodium calcium manganous ferrous phosphate, $(Ca,Mn,Fe,Na_2)_3(PO_4)_2.H_2O$, with the ratios Mn : Fe+Ca : Na$_2$(K$_2$,Li$_2$)$= 6 : 3 : 2$. H. Berman and F. A. Gonyer gave $7(Mn,Fe)O.2(Na_2,K_2,Ca).3P_2O_5.H_2O$. According to G. J. Brush and E. S. Dana, dickinsonite forms olive-green, oil-green, or grass-green, slightly dichroic masses which are foliaceous, micaceous, lamellar, radiated or stellated, as well as tabular, pseudorhombohedral, monoclinic crystals with the axial ratios $a : b : c = 1.73205 : 1 : 1.19806$, and $\beta = 61° 30'$. There are triangular striations on the (001)-face, and the (001)-cleavage is perfect. The sp. gr. is 3·338 to 3·343, and the hardness, 3·5 to 4·0. The two minerals dickinsonite and fillowite are closely related and yet have many different properties. H. Berman and F. A. Gonyer found the indices of refraction to be $\alpha = 1.648$, $\beta = 1.655$, and $\gamma = 1.662$; the optic axial angle $2V = 90°$ nearly; and the optical character is positive. L. G. Eakins, and W. P. Headden described a mineral from the vicinity of Harney City, South Dakota, and it was called **griphite**—from $\gamma\rho\acute\iota\phi o\varsigma$, an enigma. W. P. Headden represented it by the formula $5(Mn,Ca,Fe,H_2,Na_2)O.P_2O_5$. It occurs in dark brown, kidney-shaped masses, optically amorphous. Its sp. gr. is 3·401, and its hardness, 5·5. H. Berman and F. A. Gonyer described a mineral from Poland, Maine, which they called **landesite**—after K. K. Landes. The crystals are rough, with an octahedral development and a good cleavage (010). The analysis corresponds with $2Fe_2O_3.20MnO.8P_2O_5.27H_2O$. The optic angle $2V$ is large; the optical character is negative; the indices of refraction $\alpha = 1.720$, $\beta = 1.728$, and $\gamma = 1.735$; and the pleochroism α is dark brown, β is light brown, and γ is yellow. The sp. gr. is 3·026. The mineral **triploidite,** occurring at Branchville, Connecticut, was named from triplite, and $\epsilon\grave\iota\delta o\varsigma$, form. H. Laubmann and H. Steinmetz also found the mineral near Hagendorf, Bavaria. The American mineral was described by G. J. Brush and E. S. Dana. The composition approximates $4(Mn,Fe)O.P_2O_5.H_2O$, or $(Mn,Fe)_3(PO_4)_2.(Mn,Fe)OH$. It has a yellowish- or reddish-brown colour, but isolated crystals may vary in colour from topaz-yellow to hyacinth-red. There is a faint pleochroism. The monoclinic crystals have the axial ratios $a : b : c = 1.85715 : 1 : 1.49253$, and $\beta = 71° 46'$; F. Müllbauer gave for crystals from Hagendorf, Bavaria, $a : b : c = 1.8516 : 1 : 1.4885$, and $\beta = 108° 18'$. The crystals

are striated vertically, and commonly appear in aggregates more or less fibrous and columnar; the mineral may also be more or less fibrous, and nearly compact, and massive. The (100)-cleavage is perfect. The sp. gr. is 3·697, and the hardness 4·5 to 5·0. It is soluble in acids.

A. Schwarzenberg[2] prepared anhydrous **manganous pyrophosphate** by calcining one of the hydrates; J. H. Talbot, G. Berendts, W. Heintz, C. H. D. Bödeker, and H. J. Debray, by calcining the hydrophosphate; and F. J. Otto, by calcining ammonium manganous phosphate. According to A. Schwarzenberg, and G. Vortmann, if normal sodium pyrophosphate be added to a soln. of manganous sulphate, the amorphous white *trihydrate*, $Mn_2P_2O_7.3H_2O$, is formed when the washed product is dried at 100°. C. N. Pahl discussed the possible existence of an *enneahydrate*. If it be dried at 120°, the monohydrate, $Mn_2P_2O_7.H_2O$, is formed. According to O. Andersen, the anhydrous salt forms brownish-pink, prismatic crystals composed of a great number of thin prisms in parallel intergrowth. The powder is pale pink. The axial ratios of the monoclinic crystals are $a : b : c = 0.7834 : 1 : —$, and $\beta = 74° 9'$. The (110)-cleavage is perfect, but the (001)-cleavage is poor. The sp. gr. is 3·707 at 25°/4°. F. W. Clarke gave 3·5847 at 20° and 3·5742 at 26°. There is a faint pleochroism—a being light pink, and β and γ nearly colourless with a faint yellow tinge. The optic axial angle is very large; the optical character is positive. The refractive indices for sodium light were $a = 1.695$; $\beta = 1.704$; and $\gamma = 1.710$; and the birefringence $\gamma - a = 0.015$. The m.p. of the salt is 1196°, and when mixed with 75, 50, and 25 per cent. of magnesium pyrophosphate, melting at 1383°, the m.p. are respectively 1242°, 1286°, and 1340°. Hence, the crystals of manganous and magnesium pyrophosphates are isomorphous of the simple type, with no maximum or minimum (Fig. 6—1. 10, 2). The mean refractive indices of manganous and magnesium pyrophosphates are respectively 1·70 and 1·60; and for mixtures of manganous pyrophosphate with 75, 50, and 25 per cent. of magnesium pyrophosphate, the mean refractive indices are 1·67, 1·65, and 1·63, respectively. The complex ions $[Mn_2(P_2O_7)_3]''''''$ were studied by S. Freed and C. Kasper. G. Foëx and A. Brunet found that the coeff. of magnetization, 103.1×10^{-6} at 16·1°, varies inversely as the temp. at $-250°$ instead of following Curie's law. The coeff. of magnetization is constant between $-80°$ and 485°. H. Struve found that if the pyrophosphate be heated to whiteness in hydrogen, it forms manganous orthophosphate (*q.v.*), and if heated in a carbon crucible, manganese phosphide is formed. A. Schwarzenberg said that the precipitated salt is soluble in a soln. of sodium pyrophosphate; and H. Rose, not soluble in a soln. of manganous sulphate. C. N. Pahl added that the washed salt is sparingly soluble in a soln. of sodium pyrophosphate, but more soluble in a soln. of potassium pyrophosphate. C. D. Braun found that hydrochloric acid dissolves the salt, forming when warmed a bluish-violet liquid. A. Schwarzenberg found that the soln. in sulphurous acid when boiled forms tabular plates of what C. N. Pahl regarded as dihydropyrophosphate. A. Schwarzenberg found that the salt is decomposed by potash-lye, and C. D. Braun that when the precipitated salt is shaken with water and lead dioxide, a greyish-violet coloration appears. According to C. N. Pahl, if a soln. of the trihydrated salt in oxalic acid be evaporated, rhombic prisms of **manganous dihydropyrophosphate**, $MnH_2P_2O_7.4H_2O$, are formed; and the same salt is produced from a soln. of the trihydrated normal salt in sulphurous acid. The dihydropyrophosphate is soluble in water. It does not melt at a red-heat.

According to K. A. Wallroth, if ammonium sodium phosphate be melted with manganous oxide, **sodium manganous pyrophosphate**, $Na_2MnP_2O_7$, is formed; and L. Ouvrard obtained the same salt by melting an excess of sodium metaphosphate with manganous oxide, or carbonate. The prismatic crystals have a sp. gr. of 2·9 at 20°. A. Rosenheim and co-workers prepared the *tetrahydrate*, $Na_2[MnP_2O_7]$. $4H_2O$. C. N. Pahl obtained the *hemienneahydrate*, $Na_2MnP_2O_7.4\frac{1}{2}H_2O$, by adding manganous sulphate to a soln. of sodium pyrophosphate so long as the precipitate

re-dissolves. If the liquid be boiled, or if it be allowed to stand 24 hrs., prismatic crystals are deposited. It melts when heated to redness. It is sparingly soluble in water. H. Rose said that the original soln. is not precipitated by ammonia or ammonium sulphide; and C. N. Pahl, that it is not precipitated by potassium ferrocyanide. According to C. N. Pahl, if manganous pyrophosphate stands for a long time in contact with a soln. of sodium pyrophosphate, or if the mixture be warmed, sparingly-soluble crystals of **sodium manganous pentapyrophosphate**, $2Na_2P_4O_7.3Mn_2P_2O_7.24H_2O$, are formed. The salt fuses at a red-heat.

According to G. Buchner, if a 5 per cent. soln. of sodium pyrophosphate be added to a soln. of a salt of the ammonium sulphide group, a precipitate is obtained soluble in an excess of the reagent. The addition of ammonium sulphide to this soln. precipitates the metals as sulphides in the case of zinc, cobalt, nickel, and iron (ferrous and ferric), but produces no precipitate with manganese (manganous and manganic), uranium, chromium, or aluminium. When these last-mentioned soln. are heated, or allowed to stand for some time, the manganese is precipitated as pyrophosphate of manganese, ammonium, and sodium. The soln. containing aluminium and chromium become turbid if boiled and subsequently cooled; but in the case of uranium the soln. remains clear even after boiling. If a soln. of an iron salt is precipitated by ammonium sulphide, and a soln. of sodium pyrophosphate subsequently added, the ferrous sulphide dissolves when the liquid is boiled, forming a colourless soln. which becomes dark green on cooling, and finally deposits nearly all the iron as sulphide. G. Buchner thus found that **ammonium sodium manganous pyrophosphate**, $(NH_4)NaMnP_2O_7.3H_2O$, is obtained in white crystals when a soln. of manganous sulphate is mixed with sodium pyrophosphate so that the precipitated manganous pyrophosphate re-dissolves, and the soln. treated with ammonium sulphide and allowed to stand for some time or boiled. It is also produced when manganous sulphide, precipitated from a manganous sulphate soln. by ammonium sulphide and ammonia, is dissolved in a soln. of sodium pyrophosphate and allowed to stand. The addition of sodium carbonate to the soln. gives no precipitation, but potassium hydroxide precipitates manganous hydroxide. The same salt is produced when a soln. of manganic pyrophosphate in sodium pyrophosphate is treated with ammonium sulphide and boiled or allowed to stand for some time. According to F. J. Otto, the complex salt is formed if a soln. of sodium pyrophosphate is warmed with manganous sulphate and aq. ammonia, so that the flocculent precipitate forms a yellow granular powder. This can be washed with boiling water. The salt is stable in air; when heated it gives off water and ammonia; conc. potash-lye also expels ammonia; when boiled with conc. nitric acid, hydrated manganese dioxide is precipitated. The salt does not dissolve in water or alcohol, but it is easily soluble in dil. acids.

According to L. Ouvrard, if manganous oxide or carbonate be melted with an excess of potassium metaphosphate, rose-coloured prisms of **potassium manganous pyrophosphate**, $K_2MnP_2O_7$, are formed. The sp. gr. is 3·1 at 20°; and the salt is soluble in dil. acids. C. N. Pahl obtained the *octohydrate*, $K_2MnP_2O_7.8H_2O$, by adding manganous sulphate to a soln. of sodium pyrophosphate so long as the precipitate re-dissolves, and allowing the liquid to stand for some hours. The hexagonal plates or six-sided prismatic crystals readily fuse. The syrupy soln. of manganous pyrophosphate in sodium pyrophosphate furnishes colourless, microscopic, sparingly-soluble crystals of **potassium manganous tripyrophosphate**, $2K_4P_2O_7.Mn_2P_2O_7.10H_2O$. The salt fuses at a red-heat.

R. Maddrell,[3] and T. Fleitmann prepared **manganous dimetaphosphate**, $Mn(PO_3)_2$, by treating manganous sulphate or other manganous salt with an excess of phosphoric acid at 316°. The same product was obtained by T. Fleitmann by heating the hydrate at a red-heat. The white or reddish-white powder is insoluble in water and dil. acids; it dissolves in conc. sulphuric acid. It is decomposed when warmed with ammonium or sodium sulphide; and when digested with sodium carbonate soln. it forms sodium dimetaphosphate. F. Warschauer regarded

this salt as a tetrametaphosphate, and G. Tammann, as a trimetaphosphate. The *tetrahydrate*, $Mn(PO_3)_2.4H_2O$, was obtained by T. Fleitmann from a mixture of a conc. soln. of ammonium dimetaphosphate and an excess of manganous chloride, by adding alcohol, and allowing it to stand some time. G. Tammann gave the formula $1.5\{Mn(PO_3)_2\}.6.5H_2O$. T. Fleitmann, and A. Glatzel, by adding ammonium chloride to a soln. of manganous dimetaphosphate, obtained **ammonium manganous dimetaphosphate**, $(NH_4)_2Mn(P_2O_6)_2.4H_2O$, in efflorescent crystals. A. Glatzel found that 100 parts of water dissolved 1·205 parts of salt. All the water of crystallization is lost at 150°; and at a higher temp. ammonia and some phosphoric oxide are given off, and at a red-heat the salt fuses. The salt is easily decomposed by acids. A. Glatzel obtained similarly **potassium manganous dimeta-phosphate**, $K_2Mn(P_2O_6)_2.6H_2O$, in flesh-coloured crystals; 100 parts of water dissolve 1·052 parts of salt. The salt is dissolved when boiled with conc. sulphuric acid. It loses 3 mols. of water at 100°, and the remainder at dull redness, without changing its constitution. It sinters at a higher temp. and then becomes insoluble in acids. Similarly with **sodium manganous dimetaphosphate**, $Na_2Mn(P_2O_6)_2.6H_2O$, which loses its water of crystallization at 200°; it melts at a red-heat, and then becomes insoluble in sulphuric acid. Before the calcination the salt is easily dissolved by boiling, conc. sulphuric acid.

H. Rose said that sodium trimetaphosphate gives no precipitate with soln. of manganous sulphate. F. de Carli studied the glasses formed with sodium meta-phosphate. According to G. Tammann, T. Fleitmann's dimetaphosphate is **manganous trimetaphosphate**, $Mn_3(PO_3)_6$. T. Fleitmann and W. Henneberg obtained the *enneahydrate*, $Mn_3(PO_3)_6.9H_2O$, by treating a soln. of manganous chloride or sulphate with sodium trimetaphosphate. G. Tammann found that the salt melts at a red-heat, and that 100 c.c. of water at 20° dissolve 0·97 grm. of the salt. C. G. Lindboom obtained the *henahydrate*, $Mn_3(PO_3)_6.11H_2O$, in colourless triclinic prisms from a mixed soln. of sodium triphosphate and manganous chloride. The salt loses its water when heated, and does not melt below redness. It is decomposed by molten sodium carbonate; is sparingly soluble in cold and warm water; it dissolves in hydrochloric acid. The cold, aq. soln., if allowed to stand some time, or if warmed, gives a precipitate when boiled with ammonia, ammonium sulphide, sodium hydroxide, and sodium carbonate. A. Wiesler found the eq. conductivity, λ, of a soln. of $\frac{1}{4}\{Mn_2(PO_3)_6.11H_2O\}$ in v litres of water at 25° to be :

v	.	.	32	64	128	256	512	1024	2048
λ	.	.	33·6	39·7	47·8	58·0	71·3	90·3	111·7

so that $\lambda_{1024-32}=56.5$. H. Schjerning prepared **sodium manganous trimeta-phosphate**, $NaMn(PO_3)_3$, from a mixture of 2 grms. of manganic orthophosphate, 3 grms. of phosphoric acid, and 10 grms. of sodium ammonium phosphate at a dull red-heat, and washing the cold mass with water. The crystals are insoluble in water and very resistant towards dil. acids and bases. The salt dissolves without decoloration in conc. phosphoric or conc. sulphuric acid. T. Fleit-mann and W. Henneberg also prepared a sodium manganous trimetaphosphate as a precipitate from a mixed soln. of sodium trimetaphosphate and manganous chloride.

A. Glatzel prepared **manganous tetrametaphosphate**, $Mn_2(PO_3)_4$, by melting a mixture of manganous carbonate and phosphoric acid at dull redness. The needle-like crystals have a pale violet colour ; they melt at a bright red-heat. The salt is not attacked by acids ; it is decomposed by fused sodium carbonate ; and is slowly decomposed in the cold by alkali sulphides. The *decahydrate*, $Mn_2(PO_3)_4.10H_2O$, is obtained by mixing soln. of manganous chloride and sodium tetrameta-phosphate. The pale red crystalline mass loses its water of crystallization at 200°, and melts at a bright red-heat. 100 parts of water dissolve 1·02 parts of the salt ; the hydrate is sparingly soluble in acids, but dissolves in conc., boiling sulphuric acid. F. Warschauer regarded T. Fleitmann's dimetaphosphate as tetrametaphosphate.

According to H. Rose, a soln. of manganous sulphate gives a white oily precipitate when treated with sodium hexametaphosphate, and the oil dissolves in an excess of the sodium salt; ammonium sulphide precipitates manganous sulphide from the 'soln.; and F. J. Otto obtained a similar precipitate from the soln. in nitric acid. C. D. Braun found that it forms a reddish-violet soln. when warmed with hydrochloric acid, and a greyish-violet coloration when shaken with lead dioxide. A. Glatzel, and H. Lüdert prepared **manganous hexametaphosphate,** $3MnO.3P_2O_5$, or $Mn_3(PO_3)_6$, by allowing the turbid mixture obtained from conc. soln. of manganous sulphate and sodium hexametaphosphate to stand for some time. A rose-coloured sticky mass is obtained. It is slightly soluble in water—forming possibly a peptized soln. The colloid dries in air to form a pale rose-coloured glass, and if heated it yields a pinkish-grey powder. It melts at a red-heat.

G. Tammann reported **sodium manganous octometaphosphate,** $Na_2Mn_3(PO_3)_8$, to be formed by melting equimolar proportions of a manganous salt and ammonium sodium hydrophosphate. The pale rose cubic crystals form rosette groups. They have an anomalous birefringence. The salt is insoluble in acids—excepting conc. sulphuric acid; and is scarcely attacked by potassium sulphide during a week's action.

G. Tammann heated T. Fleitmann's ammonium dimetaphosphate to 200°, and treated the product for many weeks with an excess of a soln. of manganous sulphate, when a soln. of **manganous decametaphosphate,** $5MnO.5P_2O_5.12H_2O$, or $Mn_5(PO_3)_{10}.12H_2O$, is formed. The soln. gives a flocculent precipitate when treated with water, to form a sticky mass.

M. Stange reported **sodium manganous triphosphate,** $Na_3MnP_3O_{10}.12H_2O$, to be formed when a soln. of 0·37 grm. of crystalline manganous sulphate is added to a soln. of a gram of sodium triphosphate. In about five minutes fine prismatic snow-white aggregates of crystals begin to form. The salt is sparingly soluble in water; it intumesces when heated; and becomes anhydrous at a red-heat. It melts to a colourless glass. The salt which has been fused dissolves in sulphuric acid. P. Glühmann represented the composition by $Na_3MnP_3O_{10}.6H_2O$.

§ 27. Manganic Phosphates

O. T. Christensen [1] prepared **manganic orthophosphate**, $MnPO_4.H_2O$, by decomposing manganic acetate with phosphoric acid, but more conveniently by adding a conc. soln. of manganous nitrate in nitric acid to a hot, aq. soln. of phosphoric acid. The salt soon begins to form, with the evolution of nitrous fumes; and it is washed with water, and dried at 100° to 110°. The greenish-grey crystalline powder slowly loses water at 300° to 400°, and rapidly at a red-heat, with the simultaneous loss of oxygen. After calcination there remains manganous pyrophosphate. A. Travers also made this salt. According to F. Fichter and E. Brunner, manganic phosphate is very stable. A conc. soln. of manganous carbonate in phosphoric acid becomes amethyst-red when it is treated with fluorine, but the oxidation is not complete. It is assumed that fluorine acts first upon the phosphoric acid, forming monoperphosphoric acid, which readily oxidizes man-

ganous sulphate in acid soln. to manganic phosphate. J. Schmidlin and P. Massini, who first prepared monoperphosphoric acid, considered the amethyst colour to be due to permanganic acid, but spectrographic examination shows at once that the dark lines are lacking. J. Chloupek studied the potential of platinum in soln. of phosphoric acid and manganic oxide. R. H. Weber found the mol. magnetism of manganic phosphate to be 0·01084. O. T. Christensen observed that dil. nitric or dil. sulphuric acid is without action, but boiling conc. sulphuric acid forms a violet soln. which, on standing, deposits a crystalline precipitate of $Mn_2O_3.4SO_3$; conc. hydrochloric acid dissolves it slowly with the evolution of chlorine. It forms a violet soln. in molten phosphoric acid at 110° ; and at 170° to 180° more of the salt is dissolved and a dark red precipitate, probably manganic hydropyrophosphate, is formed ; at 220°, the red salt of H. Laspeyres is produced. H. Laspeyres observed that the red soln. is decolorized when heated in a platinum dish on a water-bath. No gas is developed, and a greenish-grey crystalline powder is deposited. It is insoluble in water. The salt, calcined at a dull red-heat or otherwise, forms chlorine when it is heated with hydrochloric acid. It dissolves in phosphoric acid at 100° to 110° forming an amethyst-blue syrupy liquid which, when concentrated on a water-bath, finally yields amethyst-blue, six-sided, birefringent plates insoluble in water. R. H. Weber studied the magnetic properties.

J. Meyer and J. Marck found that the violet colour produced when manganous salts are oxidized in the presence of phosphoric acid is due to the presence of **manganic trihydrodiorthophosphate,** $MnPO_4.H_3PO_4$, or *diphosphatomanganic acid* or **manganidiorthophosphoric acid,** $H_3[Mn(PO_4)_2]$, which has been prepared by the interaction of anhydrous manganic acetate and conc. phosphoric acid at 100°. The reddish-violet crystals are very unstable, and readily absorb moisture, forming manganic orthophosphate. The soln. in phosphoric acid is more stable, and when electrolyzed the manganese collects about the anode, showing that it is present as a complex anion. The acid furnishes a series of salts which furnish monoclinic dark red or violet crystals—excepting the guanidine salt, which is dark yellow. The guanidine salt is anhydrous, the other salts are red or violet. This difference is taken to indicate that the water of hydration is not contained in the complex anion, but is simply water of crystallization. The potassium salt is deliquescent, the other salts are stable in air ; they are decomposed by hot water, depositing brown hydrated manganic hydroxide. Conc. sulphuric, phosphoric, and hydrofluoric acids form violet soln. ; conc. hydrochloric acid gives a brownish-green soln. which when warmed gives off chlorine ; conc. nitric acid forms a deposit of hydrated manganese dioxide ; conc. acetic acid has no action. Dil. hydrochloric acid dissolves the salt ; dil. nitric and sulphuric acids decompose it ; oxalic acid reduces the salts to form manganous salts. The soln. in dil. phosphoric acid gradually deposit greyish-green manganic orthophosphate. Ammonium sulphide gives red manganous sulphide ; sodium hydroxide or carbonate precipitates brown manganic hydroxide ; and aq. ammonia gives a brown soln. of colloidal manganic hydroxide. Barium carbonate and sodium dihydropyrophosphate give a greyish-green deposit of manganic orthophosphate. The **ammonium dihydromanganidiorthophosphate,** $(NH_4)H_2[Mn(PO_4)_2].3H_2O$, is obtained by adding manganidiorthophosphoric acid to an ammoniacal soln. of ammonium chloride, or by mixing a soln. of ammonium hydrophosphate and manganidiorthophosphate. The *guanidine salt,* $(CN_3H_6)H_2[Mn(PO_4)_2]$, was prepared similarly ; likewise also **lithium dihydromanganidiorthophosphate,** $LiH_2[Mn(PO_4)_2].3H_2O$; **sodium dihydromanganidiorthophosphate,** $NaH_2[Mn(PO_4)_2].nH_2O$, both as the *trihydrate* and *pentahydrate* ; and **potassium dihydromanganidiorthophosphate,** $KH_2[Mn(PO_4)_2].3H_2O$. A. Yakimach also obtained this salt.

What is supposed from the analysis of R. Hermann to have been **manganic pyrophosphate** was prepared in the form of the *octohydrate,* $Mn_4(P_2O_7)_3.8H_2O$, by L. Gmelin, by the action of conc. phosphoric acid on manganosic oxide or manganese

dioxide at a red-heat; H. Laspeyres worked at 100° to 110°. R. Hermann, and H. Rose used manganic oxide; H. Rose used alkali manganates or permanganates; and A. Barreswil, and F. von Kobell used manganous salts mixed with nitric acid or nitrates. The violet mass is blue when hot. It forms a columbine-red soln. with water; F. Hoppe-Seyler examined the spectrum of the aq. soln. L. Gmelin found that the aq. soln. is not decomposed by a large excess of water, but if a soln. in 6 vols. of water be allowed to stand for a few days it becomes turbid. The aq. soln. is immediately decolorized by hydrogen sulphide or sulphurous acid. R. Hermann said that if the aq. soln. is allowed to stand a long time, it deposits light brown crystalline grains, probably of hydrated manganese dioxide. The peach-coloured mass is insoluble in all acids excepting hydrochloric acid; it is decomposed by hot potash-lye. According to V. Auger, the *tetradecahydrate*, $Mn_4(P_2O_7)_3.14H_2O$, is obtained by fusing manganese nitrate with phosphoric acid at 210°, extracting the fused mass with water, and adding alcohol to the violet-coloured extract; the salt separates as a buff-coloured, crystalline precipitate which loses $10H_2O$ at 185° and the remaining $4H_2O$ at 440°. Cold soln. of alkali hydroxide extract phosphoric acid, which appears in soln. as a pyrophosphate. Sulphuric acid dissolves it with a violet colour which becomes red on dilution. Cold phosphoric acid dissolves it; from the violet soln., which becomes rapidly colourless, the phosphate $MnPO_4.H_2O$ separates. H. Schjerning found that **manganic hydropyrophosphate**, $MnHP_2O_7$, is best obtained by adding manganic orthophosphate to molten orthophosphoric acid in a platinum crucible at 220° to 230° so long as it dissolves therein, and continuing the heating for 6 to 8 hrs. with frequent stirring until the mass has become semi-solid. While still warm this product is thrown, in small portions, into cold water, the precipitate washed until free from phosphoric acid, and dried at 97°. It is pansy-coloured and of uncertain crystalline form; it undergoes oxidation when moist, and is readily decomposed by alkalies and acids, evolving chlorine with hydrochloric acid and yielding a precipitate of a higher oxide of manganese with sulphuric and nitric acids; when heated, it loses water and oxygen and is converted into manganous metaphosphate. A. Rosenheim and T. Triantaphyllides regarded $HMnP_2O_7$ as manganipyrophosphoric acid which furnishes manganipyrophosphates analogous to the corresponding chromipyrophosphates, molybdipyrophosphates, bismuthipyrophosphates, thallipyrophosphates, and ferripyrophosphates.

P. Barbier prepared **ammonium manganic pyrophosphate**, $(NH_4)MnP_2O_7$, by heating a mixture of precipitated manganese dioxide and diammonium hydrogen phosphate made up to a paste with water: a decomposition takes place, with liberation of ammonia. The product is heated with syrupy phosphoric acid until it becomes violet. On washing out with water, an insoluble, violet powder is left. This ammonium manganic pyrophosphate is decomposed by hydrochloric acid and by alkali-lye. When heated to redness it leaves a residue of manganous metaphosphate. A. Rosenheim and T. Triantaphyllides prepared the *trihydrate*, $NH_4(MnP_2O_7).3H_2O$, by the process used for the sodium salt. O. T. Christensen prepared **sodium manganic pyrophosphate**, $NaMnP_2O_7.5H_2O$, by mixing a soln. of the acetate in glacial acetic acid with sodium pyrophosphate soln.: the salt is deposited as a red crystalline precipitate. It is also prepared by treating manganic oxide with conc. hydrochloric acid, and filtering this soln. into a soln. of sodium pyrophosphate in large excess. The salt is dried at the ordinary temp. It easily loses its water of crystallization. Manganese dioxide may also be used for this preparation, and this supports the hypothesis that when treated with hydrochloric acid the dioxide does not yield the tetra- but the trichloride. A. Rosenheim and T. Triantaphyllides prepared this salt by dropping a soln. of manganic oxide in cold, conc. hydrochloric acid into a sat. soln. of sodium pyrophosphate. H. Schjerning prepared **potassium manganic pyrophosphate**, $KMnP_2O_7$, by adding a soln. of manganic orthophosphate in molten orthophosphoric acid to molten potassium nitrate; after continuing the heating for a minute or two, the melt was poured on

to iron or stone and, when cold, treated with cold water. The new salt is somewhat darker than the pansy-coloured manganous hydropyrophosphate and more stable to acids and bases; it is insoluble in water. When heated it becomes darker and then loses oxygen; when cooled by carbon dioxide and ether it becomes much paler. A. Rosenheim and T. Triantaphyllides prepared a pale violet *pentahydrate*, $K(MnP_2O_7).5H_2O$, stable below 10°, and the *trihydrate*, $K(MnP_2O_7).3H_2O$, which is decomposed by boiling water. From it may be obtained insoluble pink **silver manganic pyrophosphate**, $Ag(MnP_2O_7).3H_2O$, and insoluble pink **barium manganic pyrophosphate**, $Ba(MnP_2O_7)_2.5H_2O$.

V. Auger prepared **manganic metaphosphate**, $Mn(PO_3)_3$, by rubbing together 200 grms. of phosphoric oxide with 100 grms. of manganese dioxide and some water. The mixture becomes hot; the blue paste is heated until it becomes hard, and is then washed with water. H. Schjerning prepared it by heating a soln. of manganic orthophosphate in molten orthophosphoric acid at 350° until the mixture becomes pasty. It is then treated with cold water. The red crystalline product when hot is pansy-coloured, and when cold pale red. It is insoluble in water. It is very stable towards acids, but is decomposed by alkali-lye. A. Travers made this salt; and L. Gmelin, and R. Hermann prepared the *hydrate*, $Mn(PO_3)_3.H_2O$, by heating to redness a mixture of manganosic or manganic oxide or manganese dioxide with an excess of phosphoric acid. P. Barbier obtained it by heating precipitated manganese dioxide with 4·5 times its weight of phosphoric acid soln. of sp. gr. 1·70 until nearly dry, then adding 2 more parts of phosphoric acid and heating until the mass acquires a peach-blossom colour. It is insoluble in water, but dissolves in hydrochloric acid with liberation of chlorine, and is decomposed by alkali hydroxides with separation of manganic oxide.

V. Auger and A. Yakimach prepared **ammonium manganic perphosphate**, $(NH_4)_2H_2MnP_2O_9$, by heating a soln. of a mixture of ammonium hydrophosphate and permanganate. Black rhombic crystals separate on cooling—*vide*, **8.** 50, 29.

Minerals containing manganous oxide are usually readily oxidized, and triphylite and lithiophilite are often covered with a brownish-black surface film. The *pseudotriphylite* of J. R. Blum [2] is an alteration product of triphylite occurring as an incrustation on the triphylite of Rabenstein, Bavaria. It approximates a **manganic ferric tetraphosphate**, $(Fe,Mn)_3P_4O_{19}.3H_2O$. W. P. Headden described a mineral from a tin mine in Pennington Co., South Dakota, with a similar composition. Analyses reported by C. W. C. Fuchs, and J. R. Blum approximate $4R'_3PO_4.9R''_3(PO_4)_2$. The **heterosite** --from ἕτερος, other or different—of F. Alluaud is a greenish- or bluish-grey, brown, or violet, massive mineral, from the pegmatite of Limoges, Haute Vienne. Its sp. gr. is 3·39 to 3·52, and its hardness 4 to 6. According to H. Berman, the optical character is positive; the optic axial angle $2V$ is small; the indices of refraction are $\alpha = 1.85$, $\beta = 1.86$, and $\gamma = 1.91$; the dispersion is fairly strong; and the pleochroism α is greenish-grey, β blood-red, and γ deep purple-red. Analyses reported by P. A. Dufrénoy, J. W. Mallet, and C. F. Rammelsberg agree with the formula $(Mn,Fe)PO_4.\frac{1}{2}H_2O$—*vide* the ferric phosphates. A purple variety from Gaston Co., North Carolina, was called **purpurite** by L. C. Graton and W. T. Schaller. Its composition is similar to that of heterosite, and approximates $(Fe,Mn)_2O_3.P_2O_5.H_2O$. The sp. gr. is 3·7, and the mean index of refraction between 1·60 and 1·65. E. S. Larson gave 1·92 for the mean index of refraction. The birefringence is strong. A. Lacroix believed that the two minerals are related like lithiophilite and triphylite, purpurite representing the members of the series with manganic phosphate predominant, and heterosite with the ferric phosphate predominant. A. Damour described a brown, massive mineral also occurring in nodules. It appears to be an impure manganic ferric phosphate from Limoges, Haute Vienne, and he called it *alluaudite*—after F. Alluaud. Its sp. gr. is 3·468; its hardness, 4 to 5; and, according to E. S. Larsen, its mean index of refraction, 1·830.

CHAPTER LXV

MASURIUM AND RHENIUM

§ 1. Eka-manganese, or Masurium, and Dwi-manganese, or Rhenium

THE periodic table of atomic weight had, until recently, two blanks corresponding
with elements of atomic number 43 and 75, belonging to the manganese family.
Following D. I. Mendeléeff's [1] nomenclature—**1. 6, 4**—these elements border on the
transition families of Group VIII, as represented in the portion of the table :

I	.	Cr 24	Mn 25	Fe 26
II	.	Mo 42	? 43	Ru 44
III	.	W 74	? 75	Os 76

The blank corresponding with element 43 belongs to **eka-manganese,** and the next
blank, corresponding with element 75, belongs to **dwi-manganese.** C. H. Bosanquet
and T. C. Keeley examined a number of minerals—psilomelanes, rhodonites, rhodo-
chrosites, and pyrolusites from various localities, polyamite, wad, manganite, and
franklinite—as well as samples of manganese extracted from tobernite and from
thorianite, and a Ru-Rh-Pd alloy from the Urals, by exposing them to cathode-ray
bombardment in the hope of finding X-ray lines of one or more of the missing
elements of the manganese family ; but not one of the minerals gave any sign of the
existence of the missing elements. I. and W. Noddack and I. Tacke, O. Zvjaginstseff,
W. Franke, and O. Berg and I. Tacke sought for the missing elements in a platinum
earth from Russia, some osmiridium, and platinum residues, as well as in samples
of columbite and tantalite. The subject was discussed by W. Prandtl, E. Rüst,
and R. Swinne. In all cases, evidence of the missing elements is alleged to have
been discovered. They accordingly called ekamanganese **masurium,** Ma, from
Masuren in East Prussia ; and dwimanganese, **rhenium,** Re, from the German Rhine.
V. Dolejsek and J. Heyrovsky considered that the evidence for dwimanganese
reported by W. Noddack and I. Tacke, and O. Berg and I. Tacke is unsatisfactory.
They inferred the existence of dwimanganese in some preparations of purified
manganous sulphate from some irregularities in the potential-current curves ; but
A. N. Campbell showed that the irregularities might also be due to the over-voltage
of hydrogen. Hence, the conclusion of V. Dolejsek and J. Heyrovsky may have
been right and the reasons wrong. V. Dolejsek and J. Heyrovsky said that chlorine
prepared by the action of hydrochloric acid on pyrolusite contains appreciable
quantities of dwimanganese as a higher volatile chloride. The subject was discussed
by M. Herszfinkiel, and N. Seljakoff and M. Korsunsky.

§ 2. The Occurrence of Masurium and Rhenium

According to W. Noddack and I. Tacke,[1] and O. Berg and I. Tacke, columbite contains 10^{-6} to 10^{-7} part of the mixture of eka- and dwi-manganese elements in the proportion $1:10$. Traces of ekamanganese were detected in sperrylite, gadolinite, fergusonite, and zircon; and traces of dwimanganese in tantalite and tungstenite. W. and I. Noddack estimated that gadolinite contained 11×10^{-7} Re; alvite, 5×10^{-7}; gadolinite, 0 to 4×10^{-7}; columbite, 2×10^{-7}; tantalite, $1 \cdot 4 \times 10^{-7}$; orangite, less than 2×10^{-7}; malacone, zircon, euxenite, risörite, blomstrandine, and fergusonite, less than 1×10^{-7}; and traces in samarskite, monazite, and orthite. No known mineral contains more than $0 \cdot 001$ per cent. of rhenium.

The following proportions of rhenium in various minerals by W. and I. Noddack are to be multiplied by 10^{-6}. Alvite, $0 \cdot 2$ to $0 \cdot 6$; gadolinite, $0 \cdot 03$ to $1 \cdot 1$; hornblende, $0 \cdot 002$; muscovite, $0 \cdot 01$; orthoclase, $0 \cdot 02$; pyroxene, $0 \cdot 002$; quartz, $0 \cdot 007$; thortveitite, $0 \cdot 06$; zircon, $0 \cdot 01$ to $0 \cdot 05$; columbite, $0 \cdot 05$ to $0 \cdot 2$; euxenite, $0 \cdot 01$; fergusonite, $0 \cdot 02$; hübnerite, $0 \cdot 01$; risörite, $0 \cdot 02$; samarskite, $0 \cdot 02$; scheelite, $0 \cdot 02$; tantalite, $0 \cdot 03$ to $0 \cdot 08$; wolframite, $0 \cdot 02$; chrome ironstone, $0 \cdot 01$ to $0 \cdot 02$; rutile $0 \cdot 01$ to $0 \cdot 02$; cassiterite, $0 \cdot 01$; arsenical pyrites, $0 \cdot 01$; arsenical nickel glance, $0 \cdot 05$; lead glance, $0 \cdot 01$; copper pyrites, $0 \cdot 02$ to $0 \cdot 08$; enargite, $0 \cdot 02$; germanite, $0 \cdot 03$; stibnite, $0 \cdot 01$; copper glance, $0 \cdot 04$; kupferschiefer, $0 \cdot 03$; magnetic pyrites, $0 \cdot 02$ to $0 \cdot 03$; marcasite, $0 \cdot 03$; molybdenum glance, $0 \cdot 05$ to $21 \cdot 0$; pentlandite, $0 \cdot 01$; pyrites, $0 \cdot 01$; lead selenide, $0 \cdot 8$; copper selenide, $0 \cdot 2$; silver glance, $0 \cdot 07$; sulvanite, $0 \cdot 005$; lead telluride, $0 \cdot 01$; troilite, $0 \cdot 004$ to $0 \cdot 04$; bismuth glance, $0 \cdot 02$; arsenical nickel, $0 \cdot 01$; domeykite, $0 \cdot 002$; meteoritic iron, $0 \cdot 006$ to $0 \cdot 01$; osmiridium, $0 \cdot 01$ to $1 \cdot 0$; platinum ore, $0 \cdot 03$ to $0 \cdot 8$; and sperrylite, $0 \cdot 02$. The primary sulphides have an average of 2×10^{-8} part of rhenium; and the silicates, 1×10^{-8} part.

As a general estimate W. Noddack and I. Tacke assumed that the earth's crust contains about 10^{-13} of ekamanganese (masurium) and 10^{-12} of dwimanganese (rhenium), as well as 7×10^{-2} of manganese, and 10^{-2} of iron; and they gave later 10^{-9} each of masurium and rhenium. F. H. Loring observed lines of the element rhenium in the X-ray spectrum of manganese phosphate. C. E. St. John said that these two elements have not yet been detected in the sun, and H. Schober discussed the subject.

§ 3. The Isolation of Masurium and Rhenium

According to W. Noddack and I. Tacke,[1] a soln. of 100 grms. of platinum earth in aqua regia was evaporated to dryness, and reduced in hydrogen. The residue of the earth, insoluble in aqua regia, was heated to redness in chlorine, and the volatile chloride dissolved in water and reduced with zinc. The products of both reductions were mixed and heated to redness in oxygen. Osmium and ruthenium tetroxides were distilled off, and on the walls of the quartz tube there collected a black film of ruthenium trioxide, a white sublimate of arsenic trioxide, and a small white deposit consisting of minute, acicular crystals. The white needles were heated in a current of hydrogen sulphide, when small spherules of molten sulphide were formed. When this product is heated in oxygen, about a milligram of small white crystals collect in the cold part of the tube. The crystals were dissolved in water, and the soln. treated with hydrogen sulphide and ammonium sulphide, which did not give a precipitate. It is assumed that the soln. contains impure ekamanganese.

According to W. Noddack and I. Tacke, the chief source of rhenium was columbite. It was treated by them as follows :

1 to 20 kgrms. of columbite were heated many hours with twice the weight of sodium hydroxide and 5 per cent. of sodium nitrate. The cooled product was exposed to air for many days and then shaken up with water to yield a 5 per cent. alkali soln. After standing, the liquid was filtered and the residue washed with 5 per cent. sodium hydroxide, NaOH. This dissolved a minimum of columbium and tantalum. The green filtrate contained manganites, and was treated with hydrogen dioxide to precipitate $MnO_2.H_2O$; and with 5 per cent. ammonium chloride, which precipitated the earthy acids and silica, titania, columbium, tantalia. The resulting filtrate of 300 litres was weakly acidified with sulphuric acid and the nitrous acid removed. A small precipitate of titanium and lead and a little silica, columbium, zirconium, tantalia, hafnia, but no rhenium came down. Hydrogen sulphide was passed in till the soln. was saturated with the gas. The sulphide precipitate was filtered off and the filtrate was treated with ammonium hydroxide and ammonium sulphide and re-acidified to 5 per cent. hydrochloric acid. These sulphides were united to the first precipitate and were heated in a stream of hydrogen to remove sulphur. The residue contained 40 per cent. Cb, Ta ; 5 per cent. Si ; 5 per cent. Ti, Zr, Hf ; 10 per cent. Fe, Co, Ni, Mn ; 30 per cent. W, Mo, Sn, V ; and 10 per cent. Cu, Pb, As, Sb, Bi, Pt, Ge, Zn, Cd ; and traces of Ir, Ru, Os. These sulphides were warmed with dilute *aqua regia*, and the sulphur and tungstic acid were filtered off. The filtrate was evaporated to drive off the nitric acid. On reduction of the residue in hydrogen there remained about one gram of substance containing 15 per cent. V ; 7, Mo ; 3, W ; 10, Pt ; 5, Pb ; 15, As ; 15, Cu ; 20, Sn, Ge, Sb, Bi ; 5, Co, Ni ; 5, Cb, Ti, Ta ; 0·2 Re. The rhenium was identified by the distinct *La*-line. This residue was treated like the osmiridium and wolfram ores, and the alkali fusion products were treated with ammonium chloride. Conc. sulphuric acid was added to the filtrate and this was again filtered. This left Co, Ni, Cu, Pt, Bi, Nb, Ta, Sn, Ge, Sb ; Pb, W, and much V remained behind. A further hydrogen sulphide precipitation gave a preparation (0·1 grm.) containing V 20 per cent., Mo 70 per cent., As 5 per cent., Cb, Sn, and Sb 3 per cent., and Re 2 per cent. When this was dissolved in *aqua regia*, filtered, freed from HNO_3 and made 5 per cent. acid, and rapidly saturated with H_2S, most of the molybdenum was precipitated as MoS_2. This precipitate contained only a trace of rhenium. The filtrate was made alkaline with ammonium hydroxide, and ammonium sulphide was added to precipitate V, Mo, As, and all the rhenium, whilst Sb and Sn remained in soln. This sulphide (15–20 mg.) was composed of V, 85 per cent., Re, 10 per cent., Mo, 3 per cent., and As, 2 per cent. The final treatment consisted in heating the reduced substance in oxygen. Most of the rhenium was driven off as a white oxide, which sublimed on the cool parts of the tube and was extracted by cutting the tube. Gadolinite and other rare-earth minerals—monazite, cerite, orthite, malacone, zirkon, alvite, thorite, and orangite—were treated in a similar manner.

J. G. F. Druce obtained about 75 mgrms. of impure oxide of dwimanganese from crude manganese sulphate by the following process :

A soln. of 100 grms. of crude sulphate in 600 c.c. of water was treated with 50 grms. of ammonium chloride and 25 c.c. of aq. ammonia of sp. gr. 0·880, and hydrogen sulphide gas was passed in for some time.   The mixture, sat. with the gas, was allowed to stand some hours before filtration.   The precipitate should have included iron sulphide and any aluminium or chromium hydroxides.   The filtrate was re-treated with hydrogen sulphide until there was no further precipitation.   This required several filtrations before a soln. was obtained which no longer gave any precipitate when sat. with the gas and allowed to stand.   The filtrate and washings were allowed to stand for several days whilst still alkaline with ammonia and sat. with hydrogen sulphide to make quite sure that all manganese had been removed.   The soln. was afterwards boiled for some minutes to remove excess of hydrogen sulphide and some ammonia, acidified with hydrochloric acid, and evaporated to dryness.   The residue was strongly heated to drive off the ammonium compounds and burn away the small quantity of sulphur formed.   The final residue was dissolved in acetic acid, and ammonium oxalate in slight excess was added to precipitate the calcium present.   The filtrate was evaporated to dryness and ignited strongly to drive off all ammonium compounds.   The residue was dissolved in hot dil. nitric acid.   The soln. was precipitated with ammonium hydroxide and the washed precipitate was dissolved in hot dil. nitric acid and evaporated to dryness again, leaving a white nitrate which was ignited to a very light brown oxide.

V. Dolejsek and J. Heyrovsky obtained a preparation of dwimanganese by introducing a small crucible containing manganese amalgam into a nearly sat. soln. of manganous sulphate, and connecting the soln. with the amalgam by a piece of platinum foil.   After several days the platinum foil was removed, rinsed with water, and the deposit washed off with conc. hydrochloric acid.   The soln. was diluted with water.   Hydrogen sulphide was then passed into the liquid, and the filtered soln. contained manganese with about 2 per cent. of dwimanganese.   E. W. von Siemens and J. G. Halske discussed the extraction of these elements from platinum ores, gadolinite, sperrylite, and molybdenite ; and W. Feit, from complex sulphide slimes.

G. Heyne and K. Moers said that the precipitation of rhenium as sulphide from soln. of its salts, and subsequent reduction of the sulphide is inconvenient, because the precipitation is not complete and the sulphide readily forms a colloid.   This can be prevented by precipitating the sulphide in a pressure flask.   Even then, as shown by W. and I. Noddack the clear filtrate contains some rhenium.   They recommend heating the rhenium concentrate in oxygen, and reducing the sublimed oxides with hydrogen.   The difficulty in the condensation of the oxide cloud was overcome by passing it through a tube fitted with electrodes on the principle of F. G. Cottrell's process for the precipitation of fumes—7. 47, 3.   The reduction of perrhenates, or of the oxide with hydrogen, gives good results.   The separation of the perrhenate was studied by W. Feit, I. Spitzin, J. A. M. van Liempt, O. Hönigschmid and R. Sachtleben, and F. Machatschki.   The process was used by W. and I. Noddack.   According to G. Heyne and K. Moers, the metal can also be precipitated from neutral or acidic soln. of its salts electrolytically.   Thus, a one per cent. soln. of potassium perrhenate acidified by sulphuric acid (1 : 5), using a current density of 0·025 amp. per sq. cm., gave in 43 hrs. 0·0232 grm. of rhenium.   If a higher current density is used, some blue oxide is also deposited on the cathode. The metal is precipitated from conc. soln. in a colloidal form by means of hydrazine hydrochloride—a reaction studied by W. and I. Noddack, and F. Kraus and H. Steinfeld.   According to G. Heyne and K. Moers, formic acid gives a blue precipitate of a lower oxide.   No metal is precipitated by the reducing agents, stannous chloride, sulphurous acid, hydriodic acid, or formaldehyde.   W. Noddack, and K. Moers showed that by heating a tungsten filament in the vapour of a rhenium halide, rhenium is deposited on the wire.   The results with nickel, platinum, molybdenum, and tantalum wires were not so good.   The vapour of rhenium peroxide can be used in place of rhenium chloride or bromide, but the deposits are not so good.

§ 4. The Physical Properties of Masurium and Rhenium

V. M. Goldschmidt[1] found that the X-radiogram of rhenium agreed with crystals in the hexagonal system having the axial dimensions $a=2·765$ A., and $c=4·470$, or $a:c=1:1·616$; and a sp. gr. of 20·53 ; C. Agte and co-workers gave $a=2·765$ A., $c=4·470$ A., and $a:c=1:1·616$; and K. Moeller gave $a=2·755$ A., $c=4·450$ A., and $a:c=1:1·615$. G. Hägg discussed the mol. vol. V. M. Goldschmidt, and W. Noddack gave 0·68 A. for the ionic diameter. The sp. gr. of masurium is estimated to be about 11·5, and the m.p. 2300° K. ; while the sp. gr. of rhenium is estimated to be about 21, and the m.p. 3300° K. I. Noddack obtained 10·4 for sp. gr. of the reduced powder of rhenium, and calculated 20 from the weight and diameter of small fused beads. C. Agte and co-workers gave 20·5. W. Biltz and K. Meisel gave 8·82 for the at. vol. of rhenium at the absolute zero.

C. Agte and co-workers found that sintered rhenium is ductile in the cold, and when warmed it can be forged, hammered, and rolled. A piece formed as a crust on tungsten wire had a tensile strength of 50·6 kgrms. per sq. mm., and an elongation of 24 per cent. ; K. Becker found the coeff. of thermal expansion of rhenium to be $0·0_5467$ perpendicular to the c-axis, and about two and a half times as great, namely $0·0_41245$ in the direction of the c-axis. C. Agte and co-workers found 3440° to be the m.p. of rhenium. W. Noddack and I. Tacke gave 0·0346 for the sp. ht. of rhenium.

W. F. Meggers and C. C. Kiess, and W. F. Meggers discussed the **spark spectrum** of masurium ; and W. F. Meggers, and P. Zeeman and co-workers, the **arc spectrum.** There are spectral lines of wave-length 3424·6, 3451·9, 3460·5, 3464·7, 4133·4, 4136·46, 4227·4, 4394·4, 4513·3, 4522·7, 4791·4, 4889·2, 4923·92, 5271·0, 5275·6, 5834·31, 6307·7, 6321·9, and 6350·7. G. Heyne and K. Moers found that the lines furnished by 0·001 grm. of rhenium were in the ultra-violet, 2215, 2276·5, 2880, 3000, 3400, 3425, 3452, 3462, and 3465 A., and in the visible spectrum, 4889·15 A. in the blue, and 5270·98 A. and 5275·57 A. in the green. These are recommended standards in the spectral recognition of rhenium. Observations were made by W. Meidinger ; and H. Schober, and F. H. Loring discussed the possible identification of the spectral lines of rhenium with those of the sun, and of η Carinæ. H. Schober and J. Birke studied the *raies ultimes* in the arc spectrum ; P. Zeeman and co-workers, the under-water spark spectrum, and the Zeeman effect ; and W. F. Meggers, A. S. King and R. F. Bacher, the structure of the spectral lines.

According to O. Berg and I. Tacke, the **X-ray spectrum** of masurium furnishes lines $K_{\alpha 1}=0·672$ A., $K_{\alpha 2}=0·675$ A., and $K_{\beta 1}=0·601$ A., and rhenium, lines $L_{\beta 2}=1·2048$ A., $L_{\beta 3}=1·216$ A., $L_{\beta 1}=1·2352$ A., $L_{\alpha 1}=1·4299$ A. ; and $L_{\alpha 2}=1·4407$ A. It is said that these lines agree well with the values calculated respectively for elements of at. numbers 43 and 75. V. Dolejsek and J. Heyrovsky added that for the element of at. number 75, two of the β-lines of the L-series of O. Berg and I. Tacke coincide with those of tungsten ; their observed values for $L_{\beta 2}$ and $L_{\beta 3}$

coincide with the $L_{\alpha1}$- and $L_{\alpha2}$-lines of thallium ; and their L_{α}-line is indistinguishable from the $K_{\alpha1}$-line for zinc. V. Dolejsek and J. Heyrovsky said that taking the K_{β}-copper line as standard, $L_{\alpha1}=1430$, $L_{\beta1}=1233\cdot3$, $L_{\beta2}=1204\cdot3$, and $L_{\gamma1}=1059$. The $L_{\alpha1}$-line could not be measured very exactly. A. Sandström, H. Beuthe, B. Polland, I. Wennerlöf, O. Berg and I. Tacke, and I. Noddack studied the K- and L-series of rhenium ; and E. Lindberg, and H. Beuthe the M-series. H. Alterthum compared the **electronic emission** of tungsten and rhenium filaments, and represented the results in terms of $i=aT^2e^{-b/T}$, where a and b are constants. Expressing the values of a in amp. per cm. per degree :

	Re	N	Mo	Th	Zr	Hf
a	200	100	65	70	4,000	55,000
b	59,500	53,100	51,100	39,400	52,400	59,500

C. Agte and co-workers found the sp. **electrical resistance** of rhenium, R ohms per cm. cube, is four times that of tungsten :

	Ta	Pb	Re	Sr	Hf	W	Mn	Os
$R \times 10^4$	0·146	0·207	0·211	0·2475	0·326	0·059	0·044	0·095

The temp. coeff. of the resistance of rhenium between $0°$ and $100°$ is $0\cdot00311$, when the corresponding values for tungsten and osmium were respectively $0\cdot0046$ and $0\cdot0042$. They also gave for the sp. resistance, R ohms per cm. cube, and the temp. coeff., a, at $T°$ K. :

$T°$ K.	83°	243°	273°	393°	393°	2405°	2690°	2985°
$R \times 10^4$	0·0494	0·154	0·198	0·211	0·261	1·25	1·30	1·34
$a \times 10^3$	3·65	3·35	3·11	3·11	3·11	2·23	2·14	1·98

W. Meissner and B. Voigt measured the resistance down to $--271\cdot8°$, and found for the ratio, r, of the resistance, R, at the observed temp. to the resistance, R_0, at $0°$; and for the estimated ratio of the resistances, $r_{\rm red}$, for the pure metals when the value of R_0 is $18\cdot9\times10^{-6}$ ohm :

	0·16°	−184·77°	−194·71°	−252·55°	−268·78°	−271·64°
r	1	0·2849	0·2474	0·110	0·110	0·109
$r_{\rm red}$	1	0·1979	0·1558	0·0017	0·0017	0·0006

Observations were also made by M. le Blanc and H. Sachse. The **electrode potential** of rhenium against a normal calomel electrode, with an electrolyte of $2N\text{-}H_2SO_4$, is $0\cdot6$ volt, so that rhenium comes between copper and thallium in the electrochemical series. This is in agreement with the behaviour of these elements towards oxidizing gases. W. H. Albrecht and E. Wedekind found the **magnetic susceptibility** of rhenium to be $0\cdot046\times10^{-6}$ mass unit, a value which does not lie between those for tungsten and osmium. L. A. Sommer and P. Karlson gave $5/2$ for the nuclear moment.

§ 5. The Chemical Properties of Masurium and Rhenium

According to W. Noddack and I. Tacke,[1] rhenium oxide volatilizes before molybdenum oxide. It is predicted that the oxides of masurium will be dark coloured and of the type MaO, Ma_2O_3, and MaO_2, which will be insoluble in acids, while the oxide MaO_3 will be soluble in water, forming an acid H_2MaO_4. It will also give an oxide of the type Ma_2O_7, of m.p. 350° to 400°; Ma_2O_7 will probably be rose or yellow. Rhenium will probably form similar oxides, and Re_2O_7 will probably melt at 400° to 500°, and be pale yellow or white in colour. Both oxides will probably form monoclinic or triclinic crystals. Analogous salts will be formed. It is probable, by analogy with chromium, that neither masurium nor rhenium will form a sulphide in dil. aq. soln. J. G. F. Druce said that the crude oxide of rhenium which he prepared is soluble in warm, dil. acids, forming colourless soln., excepting the soln. of the chloride, which is slightly yellow. Soln. of alkali hydroxide precipitate rhenium hydroxide, and the precipitate is insoluble in excess. W. and I. Noddack found that rhenium oxide was soluble in a little dil. hydrochloric acid to a colourless soln. There was no precipitate on adding the hydroxides of sodium, potassium, or ammonium. Hydrogen sulphide gave no precipitate in the cold and only a slight cloudiness on warming. Addition of ammonia and ammonium sulphide caused no change. Acidifying this gave a grey precipitate soluble in ammonium sulphide with difficulty. On heating the sulphide in a stream of hydrogen it gave a black powder, either of the metal or of a lower sulphide. This burned in oxygen on warming to an oxide which sublimed as a white powder, more volatile than MoO_3. Hydrogen sulphide converted it into a grey sulphide which reformed the oxide on heating. W. Noddack observed that ammonium phosphate gives no precipitate with nitric acid soln. of rhenium; and potassium xanthate gives a white precipitate of sulphur; potassium thiocyanate gives a yellowish rose-coloured salt which is soluble in ether; potassium ferrocyanide does not change visibly a soln. of rhenium salt.

According to W. Noddack, rhenium inflames in **oxygen** at 300°, forming a white tetroxide and yellow rhenium hemiheptoxide, Re_2O_7. K. Moers found that when heated in **air** to about 1000°, a film begins to form on both rhenium and tungsten, and if the air is diluted with an equal vol. of nitrogen, oxidation begins at about 1600°. The vapour of **water** in nitrogen attacks the metal at 1900°, but if heated in moist hydrogen to about 2000° the metal becomes passive towards water vapour even at 2300°. The attack then begins at 2500°.

Rhenium furnishes sublimates of rhenium chlorides when it is heated in **chlorine,** and of bromides when heated in **bromine** vapour. K. Moers observed that the metal is very little affected by **hydrofluoric acid** or by **hydrochloric acid**; it dissolves slowly in **sulphuric acid.** Rhenium does not react with **nitrogen** when heated in that gas, and no nitride has been prepared. W. Geilmann and F. Weibke observed that **ammonia** is oxidized by hydrogen dioxide in the presence of rhenium compounds. According to K. Moers, rhenium readily dissolves in **nitric acid.** As shown by H. Tropsch and H. Kassler, rhenium does not react with **carbon** at a high temp. to form a carbide; nor does it react with **carbon monoxide** to form a carbonyl. Carbon monoxide is reduced to methane by the action of a rhenium-copper couple. K. Moers observed that the attack of rhenium by **carbon dioxide** begins above 1600°. R. Schenk and co-workers observed that rhenium forms a carbide when heated in **methane.** K. Moers said that **mercury** does not dissolve

rhenium to form an amalgam. K. Becker and K. Moers found that the **rhenium-tungsten alloys** have a solidus curve with two eutectics—one at 2892° and 50 at. per cent. rhenium, and the other at 2822° with 67 at. per cent. rhenium. There is a maximum at 3005°, corresponding with **rhenium tritaditungstide**, W_2Re_3.

The atomic weight of rhenium.—W. Noddack and I. Tacke estimated that the at. wt. of masurium, or ekamanganese, is 98 to 99·5 ; and that of rhenium, or dwi-manganese, is 187 to 188. W. and I. Noddack obtained 188·71 for the at. wt. of rhenium from analyses of the oxide, the hexachloride, and the disulphide. O. Hönigschmid and R. Sachtleben obtained a better result from the ratio $AgReO_3 : AgBr$, namely 186·31. F. Schacherl showed that the two elements belong to the manganese family. W. H. Rothery discussed the electronic structure of masurium. F. W. Aston examined the mass spectrum of rhenium by the volatilization of its chloride. The result shows that rhenium has two isotopes of at. wt. 185 and 187, in accord with the rule that complex elements of at. wt. above 9 consist of two odd mass numbers two units apart. The ratio of the relative abundance of the heavier and the lighter isotopes is 1·62 : 1. This agrees with an at. wt. of 186·22, and this value is in accord with O. Hönigschmid and R. Sachtleben's value of 186·31, the value recommended by the International Committee on Atomic Weights for 1931. The electronic structure of rhenium corresponds with (2) in the K-shell ; (2, 2, 4) in the L-shell ; (2, 2, 4, 4, 6) in the M-shell ; (2, 2, 4, 4, 6, 6, 8) in the N-shell ; (2, 2, 4, 4, 1) in the O-shell and (2) in the P-shell, or else (2, 2, 4, 4, 2) in the O-shell and (1) in the P-shell.

Reactions of rhenium of analytical interest.—K. Moers observed that the reactions of analytical interest are the precipitation of mercury or thallium perrhenates with mercury or thallium salts ; the formation of precipitates with brucine and veratrin ; and the production of brown and green colorations by treating a sulphuric acid soln. with hydroquinone. Blue needle-like crystals are precipitated by methylene blue, and cæsium salts give characteristic crystals of cæsium perrhenate. Precipitation as ammonium perrhenate gives good quantitative results. F. Krauss and H. Steinfeld recommended the precipitation of the thallium perrhenate in acetic acid soln. W. Geilmann and co-workers obtained good precipitates with nitron—*vide infra.* The ultimate spectral lines in the spectrum of rhenium furnish a good qualitative test for the presence of rhenium.

§ 6. The Compounds of Rhenium

W. and I. Noddack [1] observed that when powdered rhenium or a lower oxide of rhenium is heated in a current of cold oxygen, a white cloud is formed which condenses to globular granules of **rhenium tetroxide**, Re_2O_8, or ReO_4 ; but if the temp. rises above 150°, some yellow oxide, R_2O_7, is formed. The product

obtained by the combustion of rhenium in oxygen is contaminated with about 10 per cent. of the yellow oxide. A crystalline structure cannot be recognized in the white globules, but they refract light strongly. The white oxide is estimated to have a sp. gr. of about 8·4. When exposed to ultra-violet light the white oxide becomes yellow, and if it be warmed, it also forms the yellow oxide. The m.p. of the white oxide is in the neighbourhood of 150°, but in the melting some yellow oxide is formed. The transformation of white to yellow oxide is very rapid in vacuo. The white oxide dissolves without decomposition in water, and it is also soluble in acids, and in potash-lye or soda-lye. It is very slightly soluble in ether. When the aq. soln. is evaporated, the yellow oxide is formed. The freshly prepared aq. soln. has an acidic reaction, and with alkali-lye it forms salts. The aq. soln. of the tetroxide has the characteristics of a soln. of a peroxide—it is easily reduced ; it colours titanium salts yellow and vanadium salts brown ; and it decolorizes permanganate owing to the reduction $Re_2O_8 \rightarrow Re_2O_7$. The constitution is probably :

$$O=\!\!\!\overset{\displaystyle O}{\underset{\displaystyle O}{\diagdown}}\!\!\! Re\!-\!O\!-\!O\!-\!Re\!\!\overset{\displaystyle O}{\underset{\displaystyle O}{\diagup}}\!\!\!=\!O$$

The dry white oxide is fairly stable. It is coloured violet by sulphur dioxide at room temp. ; and similarly also with the soln. of the white oxide in conc. sulphuric acid, and the soln. deposits a blue precipitate on standing for some time. The violet soln. is immediately decolorized when poured into water. If the violet sulphuric acid soln. is boiled, it is decolorized, and rhenium oxide is volatilized with the vapour. Hydrogen sulphide acts slowly on the aq. soln. of the tetroxide, and some sulphur is deposited ; but if the soln. be warm, rhenium sulphide is precipitated. H. V. A. Briscoe and co-workers could not confirm the existence of the tetroxide, and added that the heptoxide is the highest oxide.

An acidified soln. of the white oxide does not react with ammonium phosphate, or potassium ferrocyanide, nor does it give a coloration with potassium xanthate, and rhenium thus differs from molybdenum. The behaviour of the soln. towards potassium thiocyanate, and the greater volatility of rhenium oxide also serve to distinguish the element from molybdenum. Rhenic oxide gives no reaction with potassium iodide, and it is thus different from osmic oxide.

The yellow oxide, **rhenium heptoxide**, or **perrhenic anhydride**, Re_2O_7, is produced when rhenium burns in oxygen, or when one of the lower oxides is heated in oxygen at a temp. exceeding 150°. O. Hönigschmid and R. Sachtleben prepared it by reducing potassium perrhenate at 400° in hydrogen ; extracting the resulting black powder with water ; drying the black residue in nitrogen ; and burning it in oxygen, when the heptoxide appears as a yellow crystalline sublimate. According to W. and I. Noddack, the pale yellow oxide has a sp. gr. of 8·2 at 20°. It begins to absorb light at about 4700 A. ; the yellow colour becomes paler when it is cooled to −80°. When heated the oxide melts at 220° to form a yellow liquid, which solidifies to a yellow crystalline mass. The oxide is very volatile. It begins to sublime at 150°, *i.e.* below its m.p., in an atm. of oxygen, nitrogen, or hydrogen, to form a sublimate consisting of six-sided plates which have a high dispersion and refractive index. Small crystals sublime so rapidly that their m.p. cannot be determined. It is also difficult to measure the b.p. owing to sublimation. In a capillary tube the meniscus vanishes at about 450°, and this b.p. is greater than that at atm. press. The vapour density is 17·32 (air unity) at 520°, and the mol. wt. is therefore 490, in agreement with the formula Re_2O_7. At 800° there is some dissociation into rhenium dioxide and oxygen. W. A. Roth and G. Becker obtained −13·20 Cals. per mol. for the heat of soln. ; and 295·5 Cals. for the heat of formation of Re_2O_7 from its elements. W. and I. Noddack observed that the heptoxide is readily soluble in water, and alcohol, and less soluble in ether. The aq. soln. has an acidic reaction, and the sp. conductivity, k, and the mol. conductivity, μ, of soln. with m mols of the oxide per litre at 22° are :

m	.	0·01890	0·00945	0·00473	0·00236	0·00118	0·00059
k	.	0·006917	0·003525	0·001793	0·000904	0·000454	0·000227
μ	.	366	373	379	383	385	385

W. Feit gave for the sp. gr. of aq. soln. containing the following percentages of perrhenic acid :

$HReO_4$	0	2·93	10·91	20·00	31·85	40·67	50·29	61·00	65·12 per cent.
Sp. gr.	1·00	1·025	1·10	1·20	1·35	1·50	1·70	2·00	2·15

The aq. soln. may contain **perrhenic acid** : $Re_2O_7 + H_2O = 2HReO_4$, or else $Re_2O_7 + H_2O = H_2Re_2O_8$. If the formula of the acid be $HReO_4$, and $m = 0·0006$, and $\mu = 325$ at $22°$, the mobility of the ReO_4'-anions is 60, in agreement with the value of 69 for MnO_4' and 65 for ClO_4'. If the formula of the acid be $H_2Re_2O_8$, the calculated values of μ will be twice those just given, and the mobility of the R_2O_8''-anions will be 120. But the soln. contains no anions with a greater mobility than that of the OH'-ions. Hence, perrhenic acid is monobasic $HReO_4$. The acidity of this acid is rather less than is the case with perchloric or permanganic acids. The composition of the salts is in agreement with this formula.

If the aq. soln. be evaporated slowly to dryness, the colour becomes yellow, and ultimately the heptoxide separates out. The m.p. of the heptoxide is depressed by water. No hydrates have yet been obtained. If the heptoxide be mixed with enough water to form $R_2O_7.H_2O$, a yellow mass is formed which melts at $150°$, which can be readily undercooled, and which furnishes a yellow glass. W. Geilmann and F. Weibke noted the loss by volatilization during the evaporation of aq. soln of perrhenic acid. According to W. and I. Noddack, the heptoxide is readily oxidized to the tetroxide when it is warmed in oxygen. Reducing gases like carbon monoxide or sulphur dioxide form a lower coloured oxide, slowly in the cold, rapidly when heated. At $300°$ hydrogen forms a bluish-black dioxide, and at $800°$, metallic rhenium. In a sealed tube the heptoxide first sublimes, and it is then reduced to form a metal mirror on the walls of the tube. When heated to $300°$ in vacuo the heptoxide is reduced to a blue oxide. H. Hölemann observed that metal and oxide are formed during the electrolysis of feebly acidic and neutral soln. of potassium perrhenate with platinum electrodes, and a violet soln. is formed with strongly acidic soln., and with a mercury cathode and alkaline, neutral, and feebly acidic soln., rhenium amalgam and a black oxide are formed, but with strongly acidic soln., a violet soln. is produced.

The halogens chlorine, bromine, and iodine form numerous coloured compounds, studied by E. Enk, and F. Krauss and H. Steinfeld. The aq. soln. of the heptoxide, containing the relatively conc. perrhenic acid, dissolves the hydroxides of aluminium, zinc, and iron ; and also metallic zinc and iron, with the evolution of hydrogen. The oxidizing agents hydrogen dioxide and potassium permanganate have no perceptible action on the soln. Mild reducing agents have no perceptible action ; but the stronger reducing agents—like zinc dust and sulphuric acid, or hypophosphorous acid—colour the soln. of perrhenic acid. In the absence of oxygen the yellow colour is produced slowly in the cold and rapidly when heated. The yellow colour, due to the presence of rhenium trioxide, disappears when the soln. is shaken in air. Soluble thiocyanates colour cold, dil. soln. of perrhenic acid yellow, and warm soln. yellowish-red. The colouring agent is extracted by ether to form a rose-coloured ethereal soln. The cold, conc. soln. of perrhenic acid is coloured dark red and the hot soln. black. The colouring agent is extracted by ether to form a dark red ethereal soln.

Dry rhenium heptoxide reacts slowly with dry hydrogen sulphide, and at $80°$ rapidly, to form a black film of sulphide which to some extent protects the interior from attack. After an hour's treatment the unchanged heptoxide can be sublimed from the sulphide. If hydrogen sulphide be passed into a dil. aq. soln. of perrhenic acid, no change is perceptible, but in a few days a deposit of sulphur is formed. If the soln. be acidified with hydrochloric or sulphuric acid and treated with hydrogen

sulphide, the liquid becomes yellow and slowly deposits sulphide. The presence of oxalic, tartaric, or phosphoric acids retards the deposition of the sulphide. A cold, conc. soln. of perrhenic acid when treated with hydrogen sulphide produces first a yellow coloration, and then sulphide is precipitated; if the liquid be hot, black sulphide is precipitated. If ammonia and ammonium polysulphide be added to a dil. soln. of perrhenic acid, at first no precipitate is formed; but when the liquid is acidified with hydrochloric or sulphuric acid, the liquid is coloured deep rose, then grey, and a mixture of sulphur and sulphide is precipitated. If the unacidified soln. mixed with yellow ammonium sulphide be allowed to stand for some time, it becomes darker in colour and the rhenium is slowly precipitated quantitatively as sulphide. A conc. soln. of perrhenic acid when mixed with ammonia or alkali-lye and treated with a few drops of ammonium sulphide gives an immediate precipitation of black sulphide. A dil. soln. shows few characteristic reactions. The soln. are not readily reduced, and re-oxidation of the reduced yellow soln. occurs. If the soln. be evaporated to dryness with a strong reducing agent—say, hydrazine hydrochloride—a black product is obtained, probably the dioxide. J. H. Yoe found that rhenium salts give a red soln. with ammonium aurintricarboxylate, a pale yellow one with ammonia, and an almost colourless one with ammonium carbonate.

The salts, perrhenates, in acidified soln. behave like perrhenic acid. W. Geilmann and co-workers found that feebly acidified soln. of potassium perrhenate give with nitron a precipitate of nitron perrhenate, $C_{20}H_{16}N_4ReO_4$, and that the reaction is quantitative. A dil. soln. of perrhenic acid (1 grm. per litre) and a conc. soln. (20 grms. per litre) show the following reactions. Both soln. give no precipitate with soda-lye; potash-lye gives a white precipitate, soluble in water with a conc. soln. but not so with a dil. soln.; and similarly with baryta-water. Hydrochloric, nitric, sulphuric, and acetic acids have no perceptible action on conc. or dil. soln. Similarly also with hydrogen dioxide, and potassium permanganate and sulphuric acid. Sulphurous acid, hydrazine hydrochloride, hypophosphorous acid, and gallic acid give a yellow coloration which disappears when shaken in air when added to a conc. soln. of perrhenic acid, but no change occurs with dil. soln. Potassium cyanide, ferrocyanide, and ferricyanide have no perceptible influence on conc. or dil. soln.; but a conc. soln. with potassium thiocyanate gives in the cold a yellowish-red and when heated a black coloration which forms a red soln. in ether; with a dil. soln. of perrhenic acid in the cold a yellow colour is formed, in hot soln. a yellowish-red colour; and the ethereal soln. is rose-coloured. A mixture of sodium hydrophosphate and nitric acid has no perceptible influence on conc. or dil. soln. of perrhenic acid. Sodium thiosulphate in conc. soln. gives a white deposit of sulphur which becomes grey on standing, and in dil. soln. it gives a small white deposit of sulphur; and potassium xanthogenate and hydrochloric acid give similar deposits. Sodium azide and sulphuric acid, thiourea, urethane, sulphosalicylic acid, and diphenylsulphourea produce no perceptible change in conc. or dil. soln. Thiosincarbazide, and thiosinamine give with conc. soln. a yellow coloration which disappears on standing; with dil. soln. no change is perceptible. Potassium iodide, and sodium nitroprusside have no perceptible effect on conc. or dil. soln. Hydrogen sulphide, as indicated above, in conc. soln. produces a yellow coloration and then a grey precipitate of sulphur and sulphide, whilst with dil. soln. the yellow coloration is slowly produced and this is followed by a slow separation of a grey precipitate. With ammonia and ammonium polysulphide and conc. soln. a dark coloration slowly forms and a black sulphide separates out; with dil. soln. the reactions are similar but slower. If after the addition of ammonia and ammonium polysulphide hydrochloric or sulphuric acid be added, a conc. or dil. soln. of perrhenic acid gives an intense rose coloration, followed by the separation of a grey precipitate of sulphur and sulphide.

The aq. soln. of rhenium heptoxide has the characteristics of an acid. It dis-

solves metal hydroxides, and it can be neutralized by bases with the development of heat. The evaporation of these salts furnishes **perrhenates** analogous with the permanganates. The salts with colourless bases are colourless ; and those per-rhenates which have been prepared are usually soluble in water. The salts are very stable, and if the base is non-volatile they can be heated to redness in oxygen without decomposition ; whilst if heated in hydrogen they are reduced to form rhenium dioxide, etc. **Sodium perrhenate,** $NaReO_4$, is obtained by neutralizing a soln. of perrhenic acid with $0.1N$-NaOH to an aq. soln., using neutral red as an indicator. The soln. furnishes colourless, six-sided plates. The salt melts in oxygen at 300°, forming a colourless liquid which does not decompose at 600°. Water dissolves about 250 grms. per litre at 20°. H. Tollert found the solubility in 89.7 per cent. alcohol to be 22.42 grms. per litre at 19.5° ; and in 99.1 per cent. alcohol, 11.14 grms. per litre at 18°. If the soln. of perrhenic acid be similarly treated with potassium hydroxide, **potassium perrhenate,** $KReO_4$, is formed as a white powder consisting of rhomboidal crystals. F. Machatschki said that the crystals are probably tetragonal bipyramids with the axial ratio $a : c = 1 : 1.5823$. N. Broch found that the X-radiogram corresponds with a tetragonal lattice iso-morphous with scheelite, containing four mols. $KReO_4$, per unit lattice, and having $a = 5.615$ A., $c = 12.50$ A., and $a : c = 1 : 2.226$. The calculated density is 4.887. W. A. Roth and G. Becker found the heat of soln. to be -13.80 Cals. per mol. ; and the heat of neutralization, 13.5 Cals. per mol. of $HReO_4$. W. and I. Noddack said that the salt has a high index of refraction—F. Machatschki gave $\epsilon = 1.673$ and $\omega = 1.643$. In an atm. of oxygen the salt melts at 350°. N. A. Puschin and P. S. Tutundzic found the sp. conductivity k, the mol. conductivity μ, the transport number l of the ReO_4'-ion, and the degree of ionization a, for soln. of C mol of the salt per litre, to be :

	C	0.02	0.01	0.005	0.002	0.001	0.0005	0

Observations on the conductivity of soln. of perrhenic acid, and of potassium perrhenate, and of the transport numbers were also made by W. A. Roth and G. Becker. W. H. Albrecht and E. Wedekind gave -0.13×10^{-6} mass unit for the magnetic susceptibility of potassium perrhenate. W. and I. Noddack found that a litre of water dissolves 12.1 grms. or 0.0415 mol at 20°. The presence of potassium hydroxide or chloride lowers the solubility. N. A. Puschin and D. Kovach found that a rise of temp. from 0° to 100° increases the solubility from 0.35 to 9.44 per cent. H. Tollert found the solubility in 89.7 per cent. alcohol to be 0.302 grms. per litre at 18.5°. F. Krauss and H. Steinfeld found that a soln. of potassium perrhenate is not reduced by sulphurous acid, or by hydrogen whilst simultaneously exposed to rays of short wave-length. It is reduced to a mixture of metal and oxide by zinc and hydrochloric acid, by sodium amalgam, or by hydrazine hydrate. The salts **rubidium perrhenate,** $RbReO_4$, and **cæsium perrhenate,** $CsReO_4$, were similarly prepared, and they are less soluble in water than the potassium salt. Likewise also with **ammonium perrhenate,** NH_4ReO_4, which furnishes white six-sided plates.

Water dissolves about 120 grms. per litre at 20°. The salt is completely decomposed when heated in oxygen, ammonia is evolved, and rhenium heptoxide sublimed. H. V. A. Briscoe and co-workers prepared **copper perrhenate**, $Cu(ReO_4)_2.4H_2O$, from a soln. of copper carbonate in perrhenic acid. The *tetrahydrate* is formed when the salt is dried over calcium chloride; the dehydration curve has a break at 100° corresponding with the *hemihydrate*; the green anhydrous salt is formed at 115° to 120°; and rehydration furnishes the *pentahydrate*. Aq. ammonia or ammonia gas forms deep blue **copper tetramminoperrhenate**, $Cu(ReO_4)_2.4NH_3$, which melts and decomposes when heated. A white precipitate of **silver perrhenate**, $AgReO_4$, is formed when a soln. of silver nitrate is added to perrhenic acid. The salt appears in small, colourless, quadratic or rhomboidal plates which darken on exposure to light. Water dissolves 0·00809 mol or 3·2 grms. per litre at 20°. O. Hönigschmid and R. Sachtleben obtained it in a similar manner. The precipitate obtained by adding silver nitrate to a soln. of potassium perrhenate is contaminated with the latter salt, because both silver and potassium perrhenates are sparingly soluble. By twice recrystallizing the impure salt from its soln. in an excess of a silver nitrate soln., silver perrhenate of a high degree of purity is obtained. Like other silver salts, when silver perrhenate is melted it suffers a slight decomposition, and some rhenium oxide sublimes. According to W. and I. Noddack, if a soln. of perrhenic acid be neutralized with 0·1N-$Ba(OH)_2$, using neutral red as indicator, and the soln. crystallized, **barium perrhenate**, $Ba(ReO_4)_2$, is formed in colourless columns or rhomboids. H. Tollert found the solubility in 89·7 per cent. alcohol to be 2·45 grms. per litre at 18·5°. Freshly-precipitated neodymium hydroxide dissolves in perrhenic acid, forming a soln. which when evaporated to dryness gives very soluble, rose-coloured **neodymium perrhenate**, $Nd(ReO_4)_3$. The corresponding **mercuric perrhenate**, $Hg(ReO_4)_2$, and **thallous perrhenate**, $TlReO_4$, have been prepared. Dark pink **cobalt perrhenate**, $Co(ReO_4)_2.5H_2O$, is formed like the copper salt. The pentahydrate yields the *trihydrate* over calcium chloride; and further dehydration yields purple-blue anhydrous salt. It furnishes **cobalt tetramminoperrhenate**, $Co(ReO_4)_2.4NH_3$, which decomposes when heated. Pale green **nickel perrhenate**, $Ni(ReO_4)_2.5H_2O$, is similarly formed. The *pentahydrate* yields the *tetrahydrate* over calcium chloride, or at 100°, and the cream-coloured anhydrous salt is formed at 170°. The lilac **nickel hexamminoperrhenate**, $Ni(ReO_4)_2.6NH_3$, is produced by the action of ammonia, and this compound at 100° forms **nickel tetramminoperrhenate**, $Ni(ReO_4)_2.4NH_3$, which decomposes at a higher temp.

H. V. A. Briscoe and co-workers prepared rhenium dioxide; and by reducing rhenium heptoxide with rhenium they prepared **rhenium pentoxide**, Re_2O_5. The purple-red oxide is stable in air; it can be heated to about 300° in oxygen or in sulphur without change; it sublimes in vacuo above 300°; chloride gives a greenish-yellow vapour and brown solid; dry hydrogen chloride has no action; it is insoluble in water, and in dil. or conc. hydrochloric or sulphuric acid and in potash-lye; it dissolves in warm dil. nitric acid, and in fused potassium hydroxide; and it is reduced by sulphur or carbon about 300°. W. A. Roth and G. Becker gave 169 Cals. for the heat of formation of Re_2O_5 from its elements.

According to W. and I. Noddack, the characteristic compounds of rhenium just indicated contain septivalent rhenium, but in **rhenium trioxide**, ReO_3, the element is sexivalent. An aq. soln. is obtained by dissolving rhenium, rhenium sulphide, or a lower rhenium oxide in nitric acid. The yellowish-red soln. becomes pale yellow and stable when treated with alkali-lye, and it gives a precipitate with silver or barium salt. A similar soln. is produced by the action of strong reducing agents on a soln. of perrhenic acid. If rhenium powder be added to a molten alkali, a yellow mass is obtained resembling a yellow chromate. No change is perceptible when a conc. soln. of sodium rhenate is treated with soda-lye, but if the soln. be evaporated to dryness and the product be fused, a pale yellow mass is obtained. If this product be dissolved in cold water, it is decolorized, and the colourless soln.

contains sodium perrhenate. The yellow product in all these cases is either an acidic soln. of **rhenic acid**, H_2ReO_4, or a salt of that acid, namely, the **rhenates**, R'_2ReO_4. These substances are analogous with manganic acid and the manganates. The yellow soln. of rhenic acid and of its salts are very unstable; they are immediately decolorized when warmed, and slowly when allowed to stand in the cold. The soln. of the alkali rhenates are more stable, but they too decompose slowly in the cold. The colour of the dil. acidic soln. is pale yellow, and the colour becomes more and more reddish-yellow as its concentration increases, and it is therefore assumed that **rhenic anhydride**, ReO_3, is red, even though it has not yet been isolated. The yellow soln. of the alkali salts becomes browner on standing in air, probably owing to the formation of a brown colloidal rhenium dioxide. The decolorization of the soln. in air is complete in a few hours. If the yellow alkaline soln. is dried over phosphoric oxide in vacuo, a yellow crystalline substance, probably **potassium rhenate**, K_2ReO_4, or **sodium rhenate**, Na_2ReO_4, separates out. If hydrogen sulphide be passed into the acidic or alkaline soln., a black precipitate of rhenium sulphide is formed.

If an aq. soln. of perrhenic acid be neutralized with baryta-water, using neutral red as indicator, and an equal proportion of baryta-water be added, and the soln. evaporated in vacuo over calcium chloride, and heated to 300° in a current of nitrogen, black rhenium dioxide is formed. This product is then dissolved in 5 per cent. nitric acid. The soln. is treated with soda-lye until it has an alkaline reaction, and small four-sided plates separate out. The supernatant liquor remains yellow, showing that barium rhenate is very sparingly soluble in water. The precipitated salt is **barium rhenate**, $BaReO_4$. The same salt is formed when an alkaline rhenate soln. is treated with a barium salt. Barium rhenate soon becomes dark brown on exposure to air, and finally black. The extraction of the dark brown mass with water furnishes a soln. of barium perrhenate and residual rhenium dioxide. The decomposition of the rhenate into perrhenate and rhenium dioxide: $3K_2ReO_4+2H_2O=4KOH+ReO_2+2KReO_4$, resembles the decomposition of a manganate into permanganate and manganese dioxide. The soln. of an alkali rhenate with silver nitrate gives a white precipitate of **silver rhenate**, Ag_2ReO_4. Both barium and silver rhenates are soluble in nitric acid.

When the tetroxide is reduced, the colour changes to violet, blue, and finally black, and with the heptoxide the colour becomes first blue and then black. Similarly also with soln. of these two oxides in conc. sulphuric acid. The violet oxide is produced by passing sulphur dioxide over white rhenium tetroxide; the colour changes slowly in the cold, and rapidly at 40°. Analyses show that the violet product has a composition near $Re:O=1:0.235$, between those of ReO_3 and ReO_2 ($1:0.1696$). The violet oxide is not easily reduced by hydrogen; no perceptible action occurs in the cold, and with careful heating the blue oxide is formed, which becomes darker and darker as the temp. of the reaction is raised. As just indicated, the black dioxide is formed at 300°, and similarly when ammonium or sodium perrhenate is treated with hydrogen. In acidic soln. all reducing agents convert the perrhenates into sexivalent salts which are yellowish-red. The dark blue oxide is produced by the action of sulphur dioxide on rhenium heptoxide, and analyses show that the composition is near $Re:O=1:0.194$, which is between that of ReO_3 and ReO_2. If either the violet or the blue oxide be heated to 300° in hydrogen, a black oxide is formed, and analyses correspond with **rhenium dioxide**, ReO_2. It is supposed that in the violet and blue oxides the quadrivalent rhenium is present as violet *rhenium perrhenate*, $Re(ReO_4)_4$, and as blue *rhenium rhenate*, $Re(ReO_4)_2$. H. V. A. Briscoe and co-workers reduced soln. of potassium perrhenate with zinc, magnesium, calcium, and Devarda's alloy in acidic soln.; hydrazine hydrate; and stannous chloride, and observed that the first stage of the reduction is a yellow colloidal soln.—probably the hydrated dioxide—and the final product is the *dihydrate*, $ReO_2.2H_2O$. No rhenate was detected in the products of the reduction. N. A. Puschin studied the thermal decomposition of this oxide.

The lower oxides of rhenium have a great tendency to oxidize to the yellow heptoxide, and the oxidation occurs when the dry oxides are heated in oxygen or exposed in a moist state to oxidizing agents, or even to atm. oxygen. The violet oxide is slowly oxidized and decolorized in oxygen in the cold, and rapidly when heated. If a mixture of sulphur dioxide and oxygen be passed over the white octoxide, the colour slowly becomes violet at 0°, and the speed of the reduction increases as the temp. rises to 40°, and over 50°, say at 80°, the violet coloration does not appear. Water immediately decolorizes the violet oxide. The soln. in conc. sulphuric acid is stable if air be excluded, but it is immediately decolorized if the soln. be poured into water or dil. alkali-lye, and the heptoxide can be detected in the product. The deep violet soln. in sulphuric acid is a true soln., for it retains its colour when filtered through earthenware or membrane filters. Hence it is supposed that either a rhenium perrhenate or a **rhenium sulphate**, $Re(SO_4)_2$, is formed. When the dry violet oxide is heated in hydrogen, it is easily reduced, and, at the same time, tetroxide is volatilized. The latter, collecting on the hot walls of the containing vessel, may be reduced to form a rhenium mirror.

The blue oxide is rather more stable than the violet oxide towards oxygen, and at 100° it is oxidized by oxygen. A mixture of equal parts of sulphur dioxide and oxygen rapidly colours the warm yellow heptoxide blue. At temp. exceeding 250° a residue of the heptoxide is formed. The blue soln. of the blue oxide in conc. sulphuric acid is not at once decolorized when slowly poured into water or dil. alkali-lye, but the change occurs if the soln. be allowed to stand in air for some time or if it be warmed. The addition of nitric acid decolorizes it immediately. The blue soln. in sulphuric acid contains colloidal oxide which does not pass through an earthenware or membrane filter. Hydrogen readily reduces the blue oxide to black dioxide, and finally to rhenium.

The black oxide is readily oxidized when it is warmed in oxygen. The oxidation proceeds vigorously and with the development of a pale green flame. Water, and sulphuric acid do not act on the black oxide ; hydrochloric acid acts slowly ; nitric acid immediately oxidizes it to rhenic acid ; and hydrogen at 800° reduces it to rhenium metal.

When rhenium is heated in chlorine, it forms two volatile chlorides, namely, **rhenium hexachloride,** $ReCl_6$, in brown needles, which sublime at 150° and are hydrolyzed by water, and also what is thought to be **rhenium heptachloride,** $ReCl_7$, which is green and more volatile than the hexachloride ; with bromine vapour dark-coloured, volatile **rhenium bromide,** and with iodine vapour dark, volatile **rhenium iodide** are formed. The properties of rhenium are thus intermediate between those of tungsten and osmium.

H. V. A. Briscoe and co-workers observed that **rhenium tetrachloride,** $ReCl_4$, is the primary product of heating rhenium in chlorine ; and they observed no evidence of the existence of the hexachloride and heptachloride. They prepared **potassium chlororhenate,** K_2ReCl_6, and found that it gives precipitates with silver, mercurous, and thallous salt soln., but not with soln. of lithium, barium, magnesium, zinc, manganese, cobalt, nickel, ferrous, or ferric salts. E. Enke observed that the sp. gr. is 3·34 at 15° ; that it is stable towards potassium permanganate in acidic soln. ; it is oxidized by hydrogen dioxide in alkaline soln. ; it is not affected by sulphurous or hypophosphorous acids ; and it is decolorized by zinc in acidic soln. The corresponding **cæsium chlororhenate,** Cs_2ReCl_6, and **silver chlororhenate,** Ag_2ReCl_6, are unstable. W. Manchot and co-workers said that the reduction of the chlororhenate by zinc and acid, or in sulphuric acid at a mercury cathode, furnishes evidence of the existence of tervalent rhenium ; and when oxidized by air or oxygen, quinquevalent rhenium is probably present. Acidic soln. of the chlororhenate do not bleach indigo-blue, or reduce potassium permanganate soln., but autoxidation occurs in alkaline soln.

According to F. Krauss and H. Steinfeld, when a mixture of potassium per-

rhenate and iodide is treated with hydrochloric acid of sp. gr. 1·18, and the mixture boiled until the evolution of iodine has ceased, the **potassium rhenium chloride**, $K_2[ReCl_6]$, is formed, and it is decomposed by a large excess of water at room temp. Similarly with **thallous rhenium chloride**, $Tl_2[ReCl_6]$, which is unstable. The salt $K_4Re_2Cl_{11}$ is also formed under similar circumstances, and it may be a mixture of K_2ReCl_5 and K_2ReCl_6. Likewise also with $Tl_4Re_2Cl_{11}$. If potassium rhenate and bromide, and hydrobromic acid are employed, **potassium rhenium bromide**, K_2ReBr_6, is formed, whilst **thallous rhenium bromide**, Tl_2ReBr_6, is obtained from a mixture of thallous rhenate and hydrobromic acid of sp. gr. 1·75. H. V. A. Briscoe and co-workers prepared **potassium rhenium iodide**, K_2ReI_6, by heating potassium perrhenate with excess of potassium iodide and aq. hydrogen iodide at the b.p. of the latter, and can be separated from the dark-coloured soln. as crystals, shining black by reflected and dark chocolate-brown by transmitted light. It can be heated to 200° without decomposition. At about 210° there is slight decrepitation, but marked liberation of iodine is not evident below about 300°. At about 300° the reaction is symbolized : $K_2ReI_6 \rightarrow 2KI + Re + 2I_2$. With a limited quantity of water, a dark violet-black soln. results, which, on dilution, changes to dark brown or black and is evidently colloidal in character. Boiling this liquid leads to flocculation and the separation of a black precipitate, which, as was anticipated, proved to be hydrated rhenium dioxide. In alcohol, or ether, either hot or cold, the crystals are only slightly soluble, but they readily dissolve in acetone, from which potassium rheni-iodide may be recrystallized with acetone of crystallization. On heating in oxygen, iodide is evolved and a black residue is left, whilst in nitrogen the decomposition takes place quantitatively to potassium iodide, metallic rhenium, and iodine.

According to W. Noddack, when rhenium oxides are reduced by carbon monoxide or sulphur dioxide, green, blue, and violet oxides are produced, which on a prolonged heating form the white and yellow oxides. The soln. of the white oxide oxidizes hydrogen sulphide to sulphur, and in the presence of acids furnishes a grey precipitate of sulphur mixed with sulphide. The precipitation is not hindered by oxalic, tartaric, or phosphoric acid, and rhenium is thus unlike tungsten. If the grey sulphide be heated in carbon dioxide at 400° to 600°, unstable black **rhenium heptasulphide**, Re_2S_7, and **rhenium trisulphide**, ReS_3, are formed ; above 600° stable black **rhenium disulphide**, ReS_2, is produced. H. V. A. Briscoe obtained the disulphide by heating rhenium to redness in an excess of sulphur in a current of hydrogen sulphide ; and by heating the heptaselenide in vacuo at a red-heat the corresponding **rhenium diselenide**, $ReSe_2$, was prepared. W. Feit observed that when hydrogen sulphide is passed into a sat. soln. of potassium perrhenate, the soln. becomes yellow, but after the gas has been passing for a day the liquid becomes brown and almost opaque. When no further change occurs, and the liquid is boiled to remove hydrogen sulphide, and then concentrated by evaporation to about one-fifth its vol. at 35°, when it deposits small brown crystals ; they are a mixture of potassium perrhenate and a sulpho-salt ; with a further concentration of the soln. the crystals appear darker, and they are mixed with a dark brown precipitate of what is probably rhenium sulphide. The soln. is finally dried without a further deposit of crystals ; and the resulting dark brown mass is easily soluble in water, and it behaves like a mixture of **potassium sulphoperrhenate, and oxysulphoperrhenates**, $KReO_3S$, $KReS_4$, and $KReOS_3$. When the aq. soln. of this residue is treated with $0.05N$-Tl_2SO_4, a dark brown precipitate of **thallous sulphoperrhenate**, $TlReS_4$, is formed ; and when the filtrate is treated with more of the thallous sulphate soln., **thallous trioxysulphoperrhenate**, $TlReO_3S$, is formed. H. V. A. Briscoe and co-workers regard Feit's thallous sulphoperrhenate, $TlReS_4$, as a mixture of rhenium sulphide and thallous perrhenate. I. R. Juza and W. Biltz gave 70·5 Cals. for the heat of formation of the disulphide between 1100° and 1200°. W. Biltz and O. F. Weibke found that the precipitate obtained by the action of hydrogen sulphide on a soln. of potassium perrhenate is rhenium heptasulphide,

Re$_2$S$_7$. The sample dried for 60 hrs. at 160° to 170° was a black powder which oxidized easily in air. Its X-radiogram was too feeble to distinguish from that of rhenium disulphide. Its sp. gr. was 4·866 at 25·4°, and its mol. vol. 122. H. V. A. Briscoe and co-workers add that the black powder dissociates below its m.p. It adsorbs reversibly toluene and other organic solvents, but the adsorbtivity becomes less and less as the process of adsorption and desorption is repeated. The dried heptasulphide can be spontaneously reduced in hydrogen. The red soln. obtained by the action of hydrogen sulphide on soln. of alkali perrhenate probably contain alkali sulphoperrhenate, e.g. KReS$_4$. No sulphide between ReS$_2$ and Re$_2$S$_7$ was observed. When a soln. of this salt is treated with hydrochloric acid, the fugitive red coloration and the separation of sulphur which occurs, show that free **trioxysulphoperrhenic acid,** HReO$_3$S, is unstable. A corresponding **rhenium heptaselenide,** Re$_2$Se$_7$, was also prepared.

CHAPTER LXVI

IRON

§ 1. The History of Iron

IRON has been known from prehistoric times. Mouldering records, decaying monuments, fabulous legends, and sibylline traditions have been examined, but no one has found out how man discovered the utility of iron, or how man first learned the art of extracting the metal from its ores. Consequently, on passing backwards into the obscure regions of antiquity, the historian reaches an epoch where truth and fable are inseparably blended, and where more or less plausible guesses take the place of positive knowledge. Max Müller,[1] E. O. von Lippmann, J. Pokorny, O. Johannsen, L. Beck, L. Wilser, O. Schrader, H. Blümner, H. Haedicke, and F. H. A. von Humboldt inferred that copper was known to the Aryan nations before their separation, because the Sanscrit term *ayas* can be traced among the different peoples—**3.** 21, 1—whereas no term for iron was employed before that separation. The names for iron are different in every one of these languages. Max Müller said :

The Sanskrit term *ayas* for copper is shared in common by the Latin and Teutonic languages—Latin, *æs*; Gothic, *aiz*; Old High-German, *êr*; Modern German, *er-z*; Anglo-Saxon, *âr*; and English, *ore*. Like the Greek χαλκός, *chalkós*, which originally meant copper, but came to mean metal in general, bronze or brass, the Latin *æs*, too, changed from the former to the latter meaning ; and we can watch the same transition in the corresponding words of the Teutonic languages. *Æs*, in fact, like Gothic, *aiz*, meant the one metal which, with the exception of gold and silver, was largely used of old for practical purposes. It meant copper whether in its pure state or alloyed, as in later times, with *tin* (bronze) and *zinc* (brass). But neither *æs* in Latin nor *aiz* in Gothic ever came to mean gold, silver, or iron. It is all the more curious, therefore, that the Sanskrit *ayas*, which is the same word as *æs* and *aiz*, should in Sanskrit have assumed the almost exclusive meaning of iron. I suspect, however, that in Sanskrit, too, *ayas* meant originally the metal, *i.e.* copper, and that as iron took the place of copper, the meaning of *ayas* was changed and specified. In passages of the *Atharva Veda* (11. 3) and the *Vâgasaneyisanhitâ* (18. 13) a distinction is made between *syâmam ayas*, dark-brown metal, and *loham* or *lohitam ayas*, bright metal, the former meaning copper, the latter iron. The flesh of an animal is likened to copper, its blood to iron. This shows that the exclusive meaning of *ayas* as iron was of later growth, and renders it more than probable that the Hindus, like the Romans and Germans, attached originally to *ayas* (*æs* and *aiz*) the meaning of the metal *par excellence*, *i.e.* copper. In Greek, *ayas* would have dwindled to *es*, and was replaced by *chalkós* ; while to distinguish the new from the old metals, iron was called Homer *sídēros*. In Latin different kinds of *æs* were distinguished by adjectives, the best known being the *æs Cyprium*, brought from *Cyprus*. Cyprus was taken possession of by the Romans in 57 B.C. *Herod* was entrusted by Augustus with the direction of the Cypriani copper-mines, and received one-half of the profits. Pliny used *æs Cyprium* and *Cyprium* by itself for copper. The popular form, *cuprum*, copper, was first used by Spartianus in the third century, and became more frequent in the fourth. Iron in Latin received the name of *ferrum*. In Gothic *aiz* stands for Greek *chalkós*, but in Old High-German *chuphar* appears as a more special name, and *êr* assumes the meaning of bronze. This *êr* is lost in Modern German, except in the adjective *ehern*, and a new word has been formed for metal in general, the Old High-German *ar-uzi*, the Modern German *erz*. As *ayas* in Sanskrit assumed the special meaning of iron, we find that in German, too, the name for iron was derived from the older name of copper. The Gothic *eisarn*, iron, is considered by J. and W. Grimm as a derivative form of *aiz*, and the same scholars conclude from this that " in Germany bronze must have been in use before iron." *Eisarn* is changed in Old High-
German to *isarn*, later to *isan*, the Modern German *eisen* ; while the Anglo-Saxon *isern* leads to *iren* and iron.

It may safely be concluded, I believe, that before the Aryan separation, gold, silver, and a third metal, *i.e.* copper, in more or less pure state, were known. Sanskrit, Greek, the Teutonic and Slavonic languages agree in their names for gold ; Sanskrit, Greek, and Latin in their names for silver ; Sanskrit, Latin, and German in their names for the third metal. The names for iron, on the contrary, are different in each of the principal branches of the Aryan family, the coincidences between the Celtic and Teutonic names being of a doubtful character. If, then, we consider that the Sanskrit *ayas*, which meant, originally, the same as Latin *œs* and Gothic *aiz*, came to mean iron ; that the German word for iron is derived from Gothic *aiz* ; and that Greek *chalkós*, after meaning copper, was used as a general name for metal, and conveyed occasionally the meaning of iron, we may conclude, I believe, that Sanskrit, Greek, Latin, and German were spoken before the discovery of iron, that each nation became acquainted with that most useful of all metals after the Aryan family was broken up, and that each of the Aryan languages coined its name for iron from its own resources, and marked it by its own national stamp, while it brought the names for gold, silver, and copper from the common treasury of their ancestral home.

In agreement with this, O. Schrader could find no primeval term for iron in Indo-German antiquity ; he thinks that iron was not known until after copper (bronze), and that the Greeks became acquainted with iron in Asia Minor and the Pontine countries in the post-Mycenic and pre-Homer times. L. Beck has suggested that *ayas* may have been a general term for metals, and then came to be applied specifically to iron, just as the Grecian χαλκός, copper, came to be employed for iron— Homer's *Odyssey* (**9.** 391) ; and, according to E. B. Tylor, in Mexico the term *tepuztli* for copper came to be applied to iron—*vide infra*. According to J. Beckmann, the Greeks, at the time of Homer, applied to steel many different names. For instance, the term ζομωμα was applied to the steeled part of an instrument ; the name χάλυψ was given to steel—from Chalybes, a people on the southern shore of the Pontus Euxinus, between Colchis and Paphlagonia ; and the term ἀδάμας was applied to articles made of steel or iron—*e.g.* the helmet of Hercules mentioned by Hesiod, in his *Theogony*, and the adamantine chains, gates, and bars mentioned by later Greek poets. It was only at a still later period that the term ἀδάμας (*adamas*) was applied to precious stones. The Romans borrowed the term *chalybs* from the Greek χάλυψ, and in consequence of the use of the term *acies* (edge) in Pliny's *Historia naturalis* (**34.** 41) H. Stephanus, J. Beckmann, and C. Salmasius suggested that the Italians adopted the term *acciajo*, the Spanish *acero*, and the French *acier* for steel. O. Johannsen, indeed, said that the term for iron in all the Indo-Germanic languages comes from the Sanscrit *ayas*. According to E. O. von Lippmann, the origin of the Latin word *ferrum* for iron is not known with certainty. The origin of the term *steel* is discussed later on.

A. H. Sayce pointed out that a Hittite text of the fourteenth century B.C. speaks of " black iron of heaven from the sky." G. F. Zimmer said that nearly all the more cultured ancient people applied to iron a term which meant a " metal or something hard from heaven." Thus, the Egyptians used *ba-en-pet*, variously written :

In the cuneiform language of Assyria and Babylonia we are told that *an-bar* or *parzillu*, meaning " the metal of heaven," was written ►►┼ ►┼. Similarly, in the language of Sumeria and Chaldea, *barsa*, originally *barsal* or *barzel* respectively, and the Hebrew *barzel*, בַּרְזֶל, all have the same meaning. This, said G. F. Zimmer, indicates that " the metal of heaven " probably meant meteoric iron. G. Möller, and L. Beck have similar views about the early iron of Egypt and Assyria. J. Dümichen found *bia-n-ta*—metal of earth—in a late inscription at Denderah.

The term contrasted with *bia-n-pet* seems intended to distinguish terrestrial from celestial or meteoric iron. The name of the sixth or seventh Pharaoh of the first dynasty was Mibampes, and a component part of the name was *penipe*. Since the letters *b* and *p* are sometimes transposed, it is believed that *penipe* is equivalent to *benipe*, meaning the *Iron Pharaoh*, or "lover of iron," that is, a mighty patron of the industry, or a mighty warrior or swordsman. Such a name would not have been employed had iron not been known to the ancient Egyptians of the first dynasty. A later reading for this same Pharaoh is *Mer-ba-pen*, or "lover of this iron ":
G. F. Zimmer also argued with some probability that man first obtained iron from meteorites in several localities. He said :

It is easy to imagine that when a man of the Neolithic Age, searching for suitably shaped stones from which to form his weapons or tools, picked up an iron meteorite its abnormal weight attracted his keen interest. To him it was a stone which did not require chipping, but which could be altered in shape by hammering, and if the man or his associates had previous experience with copper, his fundamental metallurgical knowledge would be of distinct advantage to him. If he could work copper he might have known the use of fire, and if not, the mere rough shaping and then polishing the meteoric iron (which has a fine silver-like surface which does not easily rust) must have been a great success and the envy of his fellow-beings. The find and subsequent production from it, however crude it may have been, was such an advance upon his stone implements that his tribesmen all went to " search diligently for other things," and as meteorites, particularly the smaller ones, rarely fall alone, it was more than likely that others were found in the same locality.

A. F. Pott, and F. Lenormant said that the Greek term for iron, $\sigma\iota\delta\eta\rho\rho\varsigma$, or *sideros*, is related with *sidus*, a star, and this points to the meteoric origin of iron. The subject was discussed by O. Schrader, E. O. von Lippmann, etc. G. F. Zimmer said that the earliest hieroglyphic Egyptian term for iron was *min*,

and that at this time meteoric iron was found and used without the users knowing its origin. As soon as the users discovered whence it came, the name was altered to *ba-en-pet*, and judging from the time iron was in use, it must have taken over 2000 years to find this out This is not considered to be extraordinary when it is remembered that out of 300 iron meteorites known to-day, only ten have been seen to fall. It is also said that the inscription on the Unas showed that iron existed in Egypt before the fourth millennium B.C., and G. F. Zimmer considered that the first iron employed by the Egyptians was undoubtedly meteoric, because of its name. " In the most ancient religious texts, the Egyptians said that the firmament of Heaven was of iron, and this idea probably arose from its blue colour, and from the fact that meteoric iron occasionally fell from the sky."

W. Gowland, St. J. V. Day, L. Beck, and B. H. Brough consider that the assumption that telluric and meteoric iron must have been the earliest source of the metal is unnecessary, because iron ores can be so readily reduced to metallic iron in an ordinary wood or charcoal fire. J. Percy under-estimated the difficulties which would attend the manufacture of iron by primitive workers in iron, for M. Berthelot said that the delay in the use of iron is not surprising, because however numerous the deposits of ore, the extraction of the metal by smelting is a difficult operation, and one not to be performed by a people lacking some degree of trained intelligence. This subject was discussed by F. M. Feldhaus, O. Schrader, M. Hoernes, I. Lippert, G. Zippelius, S. Seligmann, E. Meyer, C. Brockelmann, F. Lenormant, H. Blümner, F. Freise, O. Stoll, M. Gsell, and C. Faulmann.

C. H. Desch said that the history of folklore and religions favours the comparatively late origin of an Iron Age culture. The superstitions attached to the

use of iron, some of which persist at the present day, and the taboos possibly imposed on it by religions, all point to the fact that iron was a newcomer and an importation into an older civilization. The common statement—by W. M. F. Petrie, T. E. Thorpe, etc.—that meteoric iron could not have been used, because it is not malleable, was shown by G. F. Zimmer to be erroneous. O. Vogel showed that in some cases natural nickeliferous iron is workable and in some cases not so. Samples of malleable meteoric iron were reported by H. A. Ward, C. U. Shepard, L. Fletcher, W. G. Owens, I. Domeyko, J. Sowerby, L. Beck, J. Johnston, A. Daubrée. J. L. Smith, W. E. Hidden, E. Cox, O. W. Huntingdon, E. H. S. Bailey, J. W. Mallet, E. Howard, H. L. Preston, G. H. Saxton, M. Donkelmann, G. Troost, O. C. Farrington, A. Goebel, E. A. de Schweinitz, O. Root, etc. The use of meteoric iron by the Esquimaux was described by J. Ross, F. Lenormant, S. Hearne, E. Sabine, C. U. Shephard, and G. F. Zimmer. G. F. Zimmer estimated that of the known samples about 99·44 per cent. are malleable and 0·56 per cent. are non-malleable. The relative weight of the evidence in favour of either hypothesis is obviously a question of temperament.

G. F. Zimmer said the idea that a bronze age followed the stone age is based on the discovery of copper and bronze utensils and weapons in ancient graves where no iron ones occur. Iron is more readily corroded than copper, and in some cases, if iron objects had decayed, the deposit of residual rust must have been obliterated by plundering. Again, iron was somewhat rare when bronze first appeared, and iron was used only in cases where bronze was not so good—say, in the cutting of harder stones. Although iron is not so suited as gold, copper, and silver for ornaments yet, according to H. Rawlinson, it was used by the ancient Chaldeans for rings and bangles, and, according to G. A. Wainwright, by the ancient Egyptians for beads, and this not necessarily because of the beauty of the metal, but rather because of its rarity—like platinum at the present day. The use of iron for rings, anklets, and other ornaments in ancient times was discussed by Pliny, in his *Historia naturalis* (**33.** 6); and more recently by P. S. P. Handcock, R. A. S. Macalister, G. Schweinfurth, D. Livingstone, H. Rawlinson, W. Jones, etc.

St. J. V. Day said that the term $\chi\alpha\lambda\kappa\acute{o}s$, which has been translated brass, corresponds with the Latin *æs*, and was used to signify any of the crude base metals, and the exact base metal was indicated by an adjective—*e.g.* red, black, grey, bright, etc.—to denote some peculiar or inherent quality by which the metal was known. Copper is mentioned only once in the Bible, namely, in *Ezra* (**8.** 27), but even then it does not mean pure copper, since the word *brass* is used by the translators for copper and bronze, and, indeed, all the alloys of copper. Zinc was unknown in biblical times, so that where brass occurs its really applies to copper or bronze. Pliny also confused copper and bronze. Hence, when a bronze age is spoken of, it would have been more correct to call it a copper age. St. J. V. Day continued, " the hypothesis that an Iron Age was not until long after copper and its alloys is founded on the most fragmentary and one-sided data." H. Schliemann also believed that the assumption of the sequence : stone, bronze, and iron, was not borne out by his observations in Mycenæ. According to J. G. Wilkinson, and G. Perrot and C. Chipiez, the mode of preparing bronze from tin and copper was discovered during the 5th or at the latest the 6th dynasty ; while W. M. F. Petrie found a bronze rod with 9 per cent. of tin which dated from the 4th dynasty.

Prehistoric iron was discussed by F. A. Anger, R. Behla, W. Belck, H. Bell, A. Bertholet, H. Blümner, J. G. L. Blumhof, J. Bohm, H. Braun, R. Bucholz, E. Cartailhac, K. Cermak, S. Clessin, St. J V. Day, J. Déchelette, W. Deecke, W. Dönitz, A. Favre, F. M. Feldhaus, M. Feyerabend, E. Friedel, J. A. N. Friend and co-workers, A. Glitsch, A. Gootze, V. Gross, P. Hahnel, F. S. Hartmann, M. Hartwich, A. Hennig, M. Heydeck, H. Hilderbrand, M. Hoernes, N. O. Holst, C. Hostmann, H. Jentsch, C. Jirecek, O. Johannsen, M. Knauthe, J. H. Krause, A. Krebs, R. Krieg, S. Krzyzankiewicz, M. Kuchenbuch, P. L. B. Kupka, E. F. Lange, A. Ledebur, F. Liger, F. Lenormant, I. Lippert, G. C. F. Lisch, A. L. Lorange, J. Lubbock, L. Martinet, C. Mehlis, H. Möntefindt and co-workers, O. Montelius, M. Much, G. Müller, J. Myers,

A. Nagel, A. Norden, O. Olshausen, M. Plath, P. Putjatin, A. Quiquerez, F. Rathgen, P. Reinecke, W. Ridgeway, H. Rupe, H. Rupe and F. Müller, O. Rygh, E. von Sacken, A. Schlez, H. Schmidt, W. Schwartz, F. Seehars, R. A. Smith, E. Soldi, A. Struck, A. Teplouchoff, T. Turner, I. Undset, M. Viedenz, R. Virchow, M. Voss, M. Wahlberg, H. Wankel, H. Hess von Wichdorff, K. Wiegand, W. M. Williams, G. Wurmbrand, G. F. Zimmer, F. X. M. Zippe, and G. Zippelius. Analyses, etc., of ancient iron or steel were made by R. A. Hadfield, H. Garland, H. Bell, H. Hanemann, H. C. H. Carpenter and J. M. Robertson, J. Myers, B. Neumann, J. A. N. Friend and co-workers, etc.

The use of iron in Egypt can be traced back to the pre-dynastic times. The graves in the cemetery of El Gerzeh examined by G. A. Wainwright, and W. M. F. Pétrie contained some iron beads which were turned completely into rust. The graves were estimated to date from about 4000 B.C. The dates for the different dynasties given by W. M. F. Petrie, E. A. W. Budge, H. Brugsch, H. R. Hall, and E. Meyer differ in some cases by as much as three centuries. Accurate dating is said to begin about 700 B.C. An analysis of the remains of the iron beads by C. H. Desch showed 10·9 per cent. of nickel, and this is taken to prove the meteoric origin of this iron, since, according to O. C. Farrington, meteoric iron contains 5 to 26 per cent. of nickel—average 7·5—whilst terrestrial iron contains only traces of nickel. A. Lucas said that the original beads may have been cut or fashioned from a natural sulphide, and the mineral was then slowly oxidized. According to E. B. Tylor, iron may have been made by chance in sundry places—a camp fire, a forest fire, or even by a stroke of lightning—and thus stray pieces of metal may have come into use before the beginning of the iron age. Herodotus alluded to a tradition that the Dactyli discovered the art of smelting iron from the accidental burning of woods on Mount Ida in Crete ; and a similar tradition ascribed the discovery of iron in Scythia to the reduction of the ore by forest fires. J. Déchelette suggested that here and there, particularly in Egypt, aboriginal smelting operations yielded little lumps of iron, which were manufactured into small objects. T. A. Rickard, however, doubted if the Egyptians had discovered how to make a pound of iron out of ore ; if they had they would have made more of it, because large deposits of iron were available in Egypt ; and it is not likely that a discovery of such importance could have been kept a secret for 2500 years.

The comparative rarity of iron in the early Egyptian tombs is not likely to have been due to a taboo on the metal, because iron objects occur in the tomb of Tut-ankh-amen, and, according to J. H. Breasted, in a sacred inscription at Abu Simel the god Ptah is made to say that he fashioned Rameses II (1194 B.C.) with limbs of electrum, with bones of bronze, and arms of *ba-n-pet*—*i.e.* iron. W. M. F. Petrie inferred that the beds of carboniferous strata on the ironstone in Sinai have been heated by eruptions of basalt and thus produced iron by the natural reduction of the ore. It is thought that the Egyptians may occasionally have found pockets of native iron in this locality.

This evidence for the use of iron in Egypt 4000 to 3500 years before the Christian era does not necessarily mean that the Egyptians then knew how to smelt iron from its ores, because the iron of that early period is more likely to have fallen from the heavens as meteorites, and not to have been deliberately manufactured. The oldest known piece of iron—not steel—of any size was found in the Great Pyramid at Gizeh in 1837 by H. Vyse ; the specimen dates from the 4th dynasty—about 3000 B.C. It was blasted out of the solid masonry near the top of the pyramid, and was afterwards deposited in the British Museum. T. A. Rickard believed that the sample of iron from Gizeh is of meteoric origin, although W. Flight, and W. Gowland believed with H. Vyse that it is of terrestrial origin. The ancient historian Herodotus, *circa* 450 B.C., stated that the granite blocks employed in constructing the Great Pyramid were shaped with iron tools, although hard rocks can be shaped with bronze, assisted, maybe, by powdered silica—a subject discussed by W. M. F. Petrie, and J. B. Beckmann. S. R. K. Glanville's estimate that iron was used for industrial purposes before 3000 B.C. is considered to be ill-founded. N. T. Belaiew favours the view of C. L. Woolley that iron was smelted from its ores

by the Sumerians during the 3rd dynasty of Ur—that is, before 2200 B.C.
C. L. Woolley reported finding a small furnace made with deeply fluted firebricks
in the long enclosure to the courtyard close by the great Ziggurat. The furnace
contained metal slag, and by it were found fragments of specular ore and some
account tablets of the time of Ibi-Sin, 2208 to 2183 B.C.

J. M. Heath—*vide infra*—and R. A. Hadfield suggested that the masonry of the
Egyptian pyramids was fashioned by means of iron and steel tools. H. Garland's
idea is that iron tools must have been employed for the finished carvings of the
Egyptian dynasty, but T. A. Rickard has pointed out that the megalithic archi-
tecture and the intricate sculpturing of the prehistoric Americans—Mitha, Mexico ;
Uxmal, Yucatan ; Copan, Honduras ; and Tihuanaco, Peru—indicate that carvings
of this kind can be done without the aid of iron tools. T. A. Joyce, O. H. Howard,
and W. H. Holmes said that the shaping of the stones in these regions was done by
means of flint, stone, or obsidian tools.

According to W. M. F. Petrie, iron did not come into general use in Egypt until
about 1200 B.C. ; or, according to H. R. Hall, about 1300 B.C. ; whilst O. Montelius
considered that iron made by man was rare as late as the 18th dynasty, *i.e.* 1580
to 1350 B.C. The period prior to this is called by W. M. F. Petrie the *Sporadic
Iron Age*, and it includes the finds at El Gerzeh and Gizeh. There are fragments
of iron picks from the Black Pyramid at Abusir, dating from the 5th dynasty,
about 3000 B.C. ; a mass of iron rust from Abydos, dating from the 6th dynasty,
about 2800 B.C. ; an iron spear-head, dating from the 12th dynasty, about 2200 B.C. ;
an iron finger-ring and an iron sickle, found below the sphinx of Horemheb
near Karnak, and dating from the 18th dynasty, about 1350 B.C. ; and an iron
halbert, probably of the time of Rameses III, three knives of Ramesside, and
a needle from Nubia, all about the 20th dynasty, about 1200 B.C. W. M. F. Petrie
discovered a wedge of iron between two copper adzes in the temple of Abydos
dating about 2800 B.C.

Iron is not mentioned in the lists of tribute collected in the 18th dynasty—
1580 to 1350 B.C.—but in the 19th dynasty iron is mentioned in the Abu Simel
inscription, indicated above, as well as on a clay tablet letter from Hattushil, king
of the Hittites, to Rameses II (1292 to 1225 B.C.), in which it is said : " Concerning
the iron about which I sent word, there is no good quality iron in the city of Kizzu-
wadni, in the house of my seal." The storing of iron under the king's seal suggests
that the metal was scarce. There is a reference to scarce and costly iron in Meso-
potamia in a contract made at the time of Hanimurabi—2067 to 2024 B.C. ; and
in the second millennium B.C., iron in Babylonia appears to have been 15 to 20 times
as valuable as copper. In the available records of the Assyrian colony at Cappa-
docia, 2300 B.C., there is no mention of iron, but, according to H. Winckler, the
people of Kisvadra (or Kizzuwadni) furnished Rameses II with iron. The
Assyrians acquired command of the region now known as Mesopotamia about 1300 B.C.
An inscription in the temple of Ammon about this time states that Menptah
captured implements of iron from the Libyans ; and an inscription concerning
the Pharaoh Thothmes III says that he captured iron helmets and iron spears
from Waharain (Mesopotamia). A doubtful translation of some ideographic writing,
1125 to 1100 B.C., at the time of Tiglath Pileser I, an early Assyrian king con-
temporaneous with Nebuchadnezzar, King of Babylon, may, according to W. Ridge-
way, and D. D. Luckenbill, refer to spears tipped with iron, but it may refer to
something else. According to W. Ridgeway, an inscription of Ashur-nasir-pal,
885 to 860 B.C., refers to hatchets of iron (*parzillu*) and of bronze (*eru*), used for
clearing a way through forests for his chariots. In this period, therefore, bronze
or copper was being displaced by iron. W. Ridgeway regarded this as the earliest
date of the use of iron by the Assyrians. According to W. M. F. Petrie, the iron
of this period came as tribute to Assyria from Chalybes, south-east of the Black
Sea. Thus, Shalmaneser II, 859–825 B.C., took iron, etc., as tribute from Chattin ;
and Rimman-Nirari III, 811 to 783 B.C., took iron, etc., as tribute from Chattin,

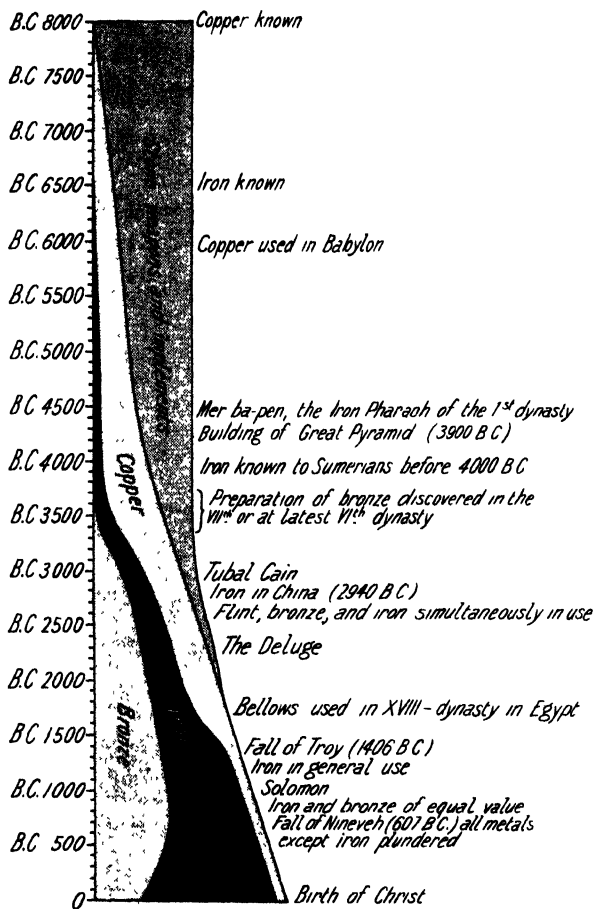
Acharru, Tyrus, Sidon, Chumri, and Palastu. A. Hertz said that iron was costly in the time of Tukulti Minurta I, 980 to 884 B.C. ; and an inscription of this period makes the first mention of iron tools. Two centuries later iron had come into industrial use, as exemplified by the find, described by L. Beck, A. H. Layard, and J. Bonomi, of an accumulation of iron bars, approximating 176 tons, in a store-room among the ruins of the palace of Sargon II, 722 to 705 B.C., at Khorsabad. W. M. F. Petrie added that iron does not frequently appear in Egypt until the 22nd and 25th dynasties—*i.e.* between 945 and 718 B.C. The heaps of iron-slag at Meroe and elsewhere in Ethiopia belong to the period succeeding 700 B.C. The


FIG. 1.—Comparative Use of Copper, Iron, and Bronze by the Ancient World.

iron tools unearthed at Thebes belong to the time of the Assyrian invasion by Ashur-bani-pal, in 666 B.C. Even in Neo-Babylonian days, 625 to 550 B.C., we are told that the use of copper for cart-wheel tyres shows that iron must have been scarce or else difficult to fabricate. Many other iron objects were likewise found in the ruins of Nineveh and Babylon. Nebuchadnezzar, 605 B.C. to 561 B.C., used iron clamps for the stone blocks employed in building a bridge over the Euphrates. Herodotus mentioned the use of iron by the Persians, and Assyrians, and also in the equipment of the army of Xerxes, who was King of Babylon from 485 to 455 B.C. Xenophon, in his *Anabasis* (5. 5), written about 400 B.C., mentioned the iron mines of the Chalybeans. The use and manufacture of iron in Western Asia was also

discussed by Marco Polo, L. W. King and H. R. Hall, A. H. Layard, J. Russegger, F. von Schwarz, and C. F. Volney ; and the use and manufacture of iron in Palestine, by L. Beck, St. J. V. Day, H. Guthe, J. Hastings, A. C. Key, R. A. S. Macalister, F. C. Movers, J. Orr, E. C. A. Riehm, D. Schenkel, G. B. Winer, and G. Zippelius.

G. F. Zimmer added that at one time iron was so rare that different nations of antiquity referred to it by talents, the same as with other precious metals. If iron had been then economically produced from its ore, it would not have been so rare ; and once the process of manufacture was discovered, the production of iron must have steadily increased, and been continuous, not sporadic, as would be the case if iron were found accidentally. W. M. F. Petrie, and others, obtained evidence that iron was freely employed for agricultural work in Egypt and Assyria about 800 B.C., and at the time of Moses iron was produced from the ore, so that the iron used in building the Great Pyramid was either telluric or meteoric, or else it was produced from the ore. The output, said G. F. Zimmer, did not at first keep pace with the demand, and the value of iron was only gradually lessened. About 607 B.C. iron had become so plentiful that in plundering the valuables at the last fall of Nineveh the iron alone was left behind. Fig. 1 represents G. F. Zimmer's idea of the comparative use of copper, iron, and bronze by the people of the ancient world, and the gradual displacement of stone by metals.

According to C. R. Conder, one of the Tel-el-Amarna tablets sent from a Hittite king to Amenshotep III—1411 to 1375 B.C.—promises iron as an extremely valuable gift. There are also an iron dagger-blade, part of an iron amuletic bracelet, and a miniature iron head-rest found in the innermost sarcophagus of Tut-ankh-amen in 1925, and described by A. Lucas, H. R. Hall, and H. Carter. These are taken to show that iron was scarce in Egypt even under the foreign domination that followed the reign of Tut-ankh-amen. These specimens of iron were considered by T. A. Rickard to be of meteoric origin, because their having resisted corrosion for so long a period is a characteristic of nickeliferous or meteoric iron. The use and manufacture of iron in Egypt were discussed by G. Belzoni, H. Blümner, St. J. V. Day, F. Delitzsch, A. Ditte, G. Ebers, A. Erman, C. Faulmann, R. Forrer, J. A. N. Friend, H. Garland, R. D. Georgi, M. Gsell, M. Hajnal, W. Heyd, M. Hoernes, F. Hommel, A. Jeremias, A. C. Key, C. B. Klunzinger, J. Lanth, O. von Lemm, R. Lepsius, H. H. Manchester, O. Olshausen, W. M. F. Petrie, R. T. Rolfe, O. Schrader, G. Schweinfurth, W. Schwenzner, E. Soldi, W. Spiegelberg, O. Stoll, A. Wiedemann, and S. Zaborowsky.

The articles on the Canaanites, chariots, iron, etc., in the *Encyclopædia Biblica* (London, 1901) have many references to the use of iron in Palestine. The old legend, referred to in *Genesis* (4. 22), describes how Tubal Cain was an instructor of every artificer in brass and iron, and the date approximates 3000 B.C., but since the writer of this, the earliest portion of Genesis, probably wrote about 950 B.C., he described his idea of things in the language of his own day, not long after the use of iron had been discovered. According to J. Hastings, the Hebrew text is correct ; it gives *tūbhal gayin*, but originally *tūbhal* stood alone ; *gayin* was a marginal explanation signifying artificer or smith. The affix *Cain* does not appear in the Greek version, and it is thought to have been added to *Tubal* to explain why the hero was regarded as the instructor of metal-workers. The name *Tubal* is supposed to refer to the Tibareni, mentioned by Herodotus as a people of Scythian stock dwelling in the mountains south-east of the Black Sea. Tubal appears to have been the eponymous hero or ancestor of the Tibarenian metal-workers. In the Bible—*Ezekiel* (27. 13)—Tubal is sometimes coupled with Meshech, who traded in " slaves and brass." Herodotus also associated the Tibareni with the Moschi (Meshki, a people of Caucasus, north of Kars). T. A. Rickard added that among their neighbours in the foothills of the Caucasus were the Chalybes, from whom the Greeks first heard of iron, which they named *Khalups*, a word, according to W. M. F. Pétrie, related to the Arabian *halaby*—tinker. Strabo refers to two tribes of Chalybes—one, living in the north-west of Armenia, was a warlike people ; and

the other, living across the mountains, was a peaceful people whose principal occupation was the manufacture of iron. Even to-day it is said that in the streets of Erzeram, in the region of the source of the Euphrates, iron is worked in the old primitive way. Tubal is identified with the Assyrian Tobal, a people of Cappadocia, living in the Caucasus region, and from whom the Assyrians obtained the iron with which they went forth to conquest. In the Hebrew text of the passage in *Genesis* (4. 22) the two metals are named *bharzel* and *nehösheth*, and these terms were translated in the Greek Septuagint as *sideros* and *chalkos* respectively. The former term refers to iron, and the latter stood for both copper and bronze. The zinc-copper alloy *brass* was unknown to the ancients of Palestine or of Greece ; but we are told that in Old English prior to the eighteenth century *brass* stood for any impure copper: Hence, the scholars tell us that the rendering of the passage in *Genesis* (4. 22) in modern English is " Tubal, the father of all such as forge copper and iron." *Enoch* (8. 1) also mentioned the general tradition that the first metalworker was a god, and that the fallen angel Azazel was a teacher of the art.

The Philistines entered Palestine before the Israelites, and there were numerous petty skirmishes between the two tribes. The references in *I Samuel* (13. 19–22) indicate that the Philistines were acquainted with iron, and that they kept the Israelites in ignorance of the method of working the metal. As R. A. S. Macalister pointed out, when the Philistine dominion was broken up, and David was on the throne, the use of iron became general. This is shown by the references in *I Samuel* (17. 7), *II Samuel* (12. 31), *I Chronicles* (22. 3 ; 29. 7), *II Chronicles* (2. 7), and *I Kings* (6. 7) to the armour of Goliath in his fight with David, to the building of Solomon's temple, and to the torture of the people of Rabbah. W. Ridgeway does not consider that the reference to the iron bedstead or sarcophagus of Amorite Og, King of Bashan (*Deuteronomy*, 3. 11), proves that the people of Canaan were working iron when the Israelites came out of Egypt. According to J. H. Gladstone, and F. J. Bliss, the excavations at Lachish, a city of the Amorites, show that iron does not appear in the remains earlier than 1250 B.C.—nearer 1000 B.C., in fact. The references in *Judges* (1. 19 ; 4. 3), *Joshua* (17. 16), and *Nahum* (2. 4), show that the Canaanites had a military advantage over the Israelites in possessing chariots of iron ; and from *Deuteronomy* (8. 9) it would appear that the Canaanites obtained their iron from the mountains of Lebanon, where smelting was conducted from early times. *Jeremiah* (15. 12) also speaks of " iron coming from the north," and J. Beckmann considers that this means " steel from the Chalybes."

The use and manufacture of iron in Western Asia were discussed by M. Firdusis, F. Freise, P. Deussen, O. Schrader, E. O. von Lippmann, G. Zippelius, R. Forrer, M. Hoernes, J. Hoops, H. Hanemann, E. Meyer, W. Ruge, M. I. Rostovtzeff, A. Jeremias, R. Lepsius, F. Cumont, and C. Thulin.

There are many other Biblical references to iron—*e.g. Job* (19. 24 ; 20. 24 ; 41. 7), *Proverbs* (27. 17), *Jeremiah* (1. 18 ; 15. 12), *Isaiah* (60. 17), *Psalms* (18. 34, 35), and *II Samuel* (22. 35). The references in *Amos* (1. 3), *Jeremiah* (17. 1), *Isaiah* (45. 2), *Ezekiel* (4. 3), and *Micah* (4. 13) show that iron may have been known to the Hebrews and Syrians. The references in *Deuteronomy* (4. 20), *I Kings* (8. 51), and *Jeremiah* (11. 4) show that smelting furnaces were known to the later Hebrew writers. It is probable that the Israelite slaves of Egypt laboured at the iron furnaces, and the iron furnace is used as an allegorical figure expressing intense suffering. Indeed, Diodorus, in his *Bibliotheca historia* (30 B.C.), represents the labour of the slaves at the iron furnaces of Greece as the most intolerable of all tyrannies.

The archæologists have discussed whether the iron in ancient Egypt was introduced from one of the neighbouring countries of the Middle East, India, or even China, or whether the Egyptians themselves discovered the modes of extracting and treating the metal. T. A. Rickard thus summarized the available information concerning the early manufacture of iron from terrestrial ore : the art did not originate in the valley of the Nile, nor in the valley of the Euphrates, for neither

was a mining region. In agreement with the myths narrated by the Greek historians, and Hebrew traditions as exemplified by the tale of Tubal, the smith, the original home of metallurgy in the ancient world was the mountainous country between the Caspian and the Black Seas. The Amorites and the Hittites, the Dactyli—mentioned by Strabo and Diodorus—the Chalybes—mentioned by Æschylus—and the Phrygians—mentioned by Herodotus—are links in the story of prehistoric metal culture. Although the first production of iron is associated with the Anatolian area, the use of the metal is connected with the extension of the Hittite power into the Syrian lowlands after 1400 B.C., and the widening use of iron was probably associated with the disintegration of the Hittite empire. According to H. Obermaier, the Assyrians obtained their metal from the Caucasus, and the Hittites brought iron into Syria. According to J. de Morgan, the tribes bordering on Armenia and Cappadocia, in the foothills of the Caucasus, discovered the art of smelting iron, where it is possible that the chance admixture of manganese may have yielded a metal of marked excellence. W. Ridgeway said that the Philistines brought iron from these countries into Palestine, and it was there that W. M. F. Petrie, in 1927, discovered the oldest specimens of undoubtedly man-made iron, for in a mound at Gerar, nine miles from Gaza, he found iron-smelting furnaces and agricultural implements, all of which had been made on the spot. These discoveries were dated by means of contemporaneous scarabs and amulets of Egyptian origin ; some iron knives are believed to go back to 1350 B.C., and the remains of the furnaces to 1194 B.C.

According to J. G. Wilkinson, the frescoes in the Egyptian tombs of Beni-Hassan (Fig. 2) show that prior to the 18th dynasty the draught in the Egyptian

FIG. 2.—Mouth Blowpipe depicted on Egyptian Tombs.

FIG. 3.—Bellows depicted on Egyptian Tombs.

metal furnaces was produced by blowpipes, and four to six men were required for the smelting operations. The mouth blowpipes were made of reeds tipped with clay, and only small pieces of metal could thus be melted. Bellows were probably introduced about the 18th dynasty. Fig. 3 is from a tomb of the period of Thothmes III, about 1500 B.C. These primitive bellows consisted of a flat pot covered with, presumably, goatskin ; there was a hole in the middle of the skin which could be closed by the heel of the operator so as to form a kind of valve ; when the valve was released by the heel, the skin was pulled up by a cord in the worker's hand. Similar bellows are used to-day by some remote tribes in India for the manufacture of iron. The primitive furnaces, or air bloomeries, were erected on high grounds in order that the wind might assist combustion. F. D. Hartland examined the remains of an ancient iron-works at Sarabit-el-Khadem, near Ayun Musa, by the Red Sea. The furnaces are thought to have been on the Catalan system, but the ore was imperfectly worked, since 53 per cent. of iron occurs in the slag-heaps. This makes it appear as if no complete smelting was employed, but only a process of fusion.

The general results show that iron was comparatively rare in Egypt until about

1300 B.C., and that before this iron was used sporadically ; only about half a dozen specimens remain to us—described by J. A. N. Friend, and H. Garland—which can be definitely shown to belong to the period prior to 1300 B.C. Although during this period the Egyptians knew how to extract iron by smelting, it was not until about 1200 B.C. and onwards that the Egyptians realized the plentiful distribution of the ore, the ease with which the metal could be extracted, and the uses to which that metal could be applied in their daily work. H. C. H. Carpenter and J. M. Robertson examined metallographically many specimens of ancient Egyptian implements, and as a result concluded that carburizing, quenching, and heat treatment generally were practised by the Egyptians many centuries before the Christian era. N. T. Belaiew pointed out that a great change in the treatment of metals in Egypt occurred in the 18th and 19th dynasties ; and that in the 19th dynasty the Egyptians were brought into contact with the Hittites and other peoples of Asia. Hence, although the Egyptians were acquainted with iron imported from Asia, they were not so well acquainted with the heat-treatment of iron. This they learned from the Hittites after the battle of Kadesh. The smelting of iron was probably begun about 1400 B.C. in the Hittite uplands between the Taurus and the Caucasus. Because of the proportion of contained nickel, it is inferred that all iron of earlier date is of meteoric origin.

According to C. Davenport, and W. Jones, legend has it that the nails used in the crucifixion of Christ were of iron, and the iron band in the Corona Ferrea, or Crown of Lombardy, was made from these very nails. There are several references to iron in the *Koran*, written in the early part of the seventh century—*e.g.* in the *Suras* (**17.** 53 ; **18.** 95 ; **22.** 21 ; **34.** 10 ; and **57.** 25). Mahomet said : " Dire evil resideth in iron as well as advantage to mankind." Herodotus made a similar statement. E. Wiedemann gave an account of the contributions of the Arabian writer Al Dimaschqui, about 1320, to the history of iron in Arabia—a subject discussed by A. von Kremer, F. Wüstenfeld, E. Meyer, W. von Gravenberch, A. Ilg, W. Heyd, and O. Stoll.

According to P. Neogi, certain passages in the *Yajuveda* indicate that iron was worked in India about 2000 B.C. Later, between 500 and 200 B.C., iron appears to have been largely used in India, more especially for warlike weapons. Probably, however, the most remarkable instance of its employment appears in a medical work describing nearly one hundred surgical instruments used for most delicate operations, which seems to show that the manufacture of steel must have been well understood. Iron swords and daggers have been unearthed from certain burial sites in Tinnevelly ; but though their exact age cannot be fixed, they are believed to have come down from prehistoric times, and specimens of third-century iron have been recovered from Buddha Gaya. According to C. von Schwarz, the manufacture of cast steel can be traced in India back to about 600 B.C., because fragments of weapons made of cast steel have been found in the Tombs of Wurri-Goan, Central India (about 5C0 B.C.). The metal was smelted in crucibles, and the hardened steel, called *kurs*, was transported to Damascus as raw material for the manufacture of the Damascus blades of the Middle Ages. A. K. Coomaraswamy also stated that the great antiquity of iron in India in the Vedic period is illustrated by constant references to iron in the Vedic literature, and in the latest of the four Vedas, the Atharvaveda, 1200 to 1000 B.C., iron is mentioned several times. I. E. Lester said that the use of iron between 1400 B.C. and 1000 B.C. was noted by R. C. Dutt. The old historian Herodotus stated that the Indian army of Xerxes carried arrows tipped with iron, so that iron was used for military purposes 500 B.C. The word *ondanique* which occurs in Marco Polo's travels originally referred to Indian steel, and the word is said to be a corruption of the Persian *hundwaniy*.

The Indian native processes for iron and steel were described by F. Buchanan, B. Heyne, etc.—*vide infra*, the history of the blast furnace. For a discussion on Wootz steel and Damascus steel, *vide infra*. J. M. Heath referred to the great antiquity of the iron and steel industry in India in these words :

The antiquity of the Indian process is no less astonishing than its ingenuity. We can hardly doubt that the tools with which the Egyptians covered their obelisks and temples of porphyry and syenite with hieroglyphics were made of Indian steel. There is no evidence to show that any of the nations of antiquity besides the Hindoos were acquainted with the art of making steel. The references which occur in the Greek and Latin writers on this subject served only to better their ignorance of it ; they were acquainted with the qualities and familiar with the use of steel, but they appear to have been altogether ignorant of the mode in which it was prepared from iron. The edges of cutting instruments of the ancients were all formed of alloys of copper and tin, and we are certain that tools of such an alloy could not have been employed in sculpturing porphyry and syenite. Quintus Curtius mentioned that a present of steel was made to Alexander of Macedon by Porus, an Indian chief whose country he had invaded. We can hardly believe that a matter of about 30 lbs. weight of steel would have been considered a present worthy of acceptance of the conqueror of the world had the manufacture of that substance been practised by any of the nations of the West in the days of Alexander. In view of the maritime intercourse between Egypt and the East, it appears reasonable to conclude that the steel of the South of India found its way by these routes from the country of Porus to the nations of Europe and Egypt. Consequently, the claims of India to a discovery which had exercised more influence upon the arts conducive to civilization and the manufacturing industry than any other within the whole range of human invention is altogether unquestioned.

There are numerous reports—A. Cunningham, St. J. V. Day, V. A. Smith, G. Cumming, etc.—on the famous iron pillar at Delhi, India—the *Delhi pillar*. It is 23 ft. 8 in. long, and 22 ft. is vertically above the ground ; its upper diameter is $12\frac{1}{2}$ in., and its lower diameter is $16\frac{1}{2}$ in., while its total weight is estimated to be about 6 tons. It has been stated that it dates back to 912 B.C., but later estimates give A.D. 300 as being nearer the mark. The pillar is usually said to show no symptom of rust. It bears an inscription in Sanscrit : " The triumphal pillar of Rajah Dhava, A.D. 310, who wrote his immortal fame with his sword." Numerous legends have grown about the pillar. The pillar is not now on its original site, but was moved to its present position about A.D. 1052 so as to form an adjunct to a group of temples. According to R. A. Hadfield, the analysis of the metal is : 0·080, C ; 0·046, Si ; 0·006, S ; 0·114, P ; 0·000, Mn ; 0·032, N ; and Fe, 99·720 ; the sp. gr. is 7·81 ; and Brinell's hardness, 188. The microscope reveals the presence of large grains of ferrite, with very small portions of cementite sometimes located in the ground mass and sometimes in the grain junctions.

Another iron pillar, the *Dhar pillar*, was erected at Mandu, about 22 miles from Dhar or Dhara, the ancient capital of Malava. It was probably entire in A.D. 1304, but was thrown down and broken in two by the Mohammedans ; about A.D. 1405 the larger piece was erected at Dhar. This was knocked down about 1531 and broken into two pieces. There are thus three portions scattered in the town. The total length of the whole piece must have been at least 43 ft. 4 in. The average section is $10\frac{1}{4}$ to $10\frac{1}{2}$ in., but the base is slightly bulbous and is 11 to $11\frac{1}{4}$ in. wide, 2 ft. from the end. The octagonal section is very irregular in form. The pillar has been described by V. A. Smith, H. G. Graves, R. A. Hadfield, H. Cousens, etc. R. A. Hadfield described another iron column known as *Khan Baba*, in Besh, in the Bhilsa District, Gevalior State, India ; it bears the inscription : " This Pillar was erected by a Greek called Heliodorus, son of Dion, who was an ambassador despatched by the Greek king Antialkidas to the court of an Indian Prince named Bhagabhadra, who ruled over Central India." It is believed to have been fixed about 125 B.C. There are a number of iron beams—*the Konarak beams*—from the Black Pagoda, at Konarak, in the Madras Presidency. They have been described by V. A. Smith, J. Ferguson, H. G. Graves, J. A. N. Friend and W. E. Thorneycroft, etc. The temple probably dates back to the thirteenth century, and the beams were used as supports for the lintels of the doorway, etc. The temple is in ruins, and the beams scattered about have been broken by the fall. The beams were made by welding up small blooms about 3 to 4 lbs. in weight. There are numerous slag inclusions in the metal. J. A. N. Friend and W. E. Thorneycroft gave for the analysis : 0·110, C ; 0·100, Si ; 0·024, S ; 0·015, P ; and Mn, a

trace. The Brinell's hardness is near 72. The metal is rather more resistant to corrosion than is the case with ordinary mild steel.

The use and manufacture of iron in India were discussed by Ismail Ibn'Ati Abulfeda, R. Andrée, J. Babington, Ibn Batuta, N. T. Belaiew, I. Benzinger, S. U. Syed Ali Bilgrami, G. C. M. Birdwood, A. Bose, B. H. Brough, W. Cracroft, J. Danvers, W. Denison, F. M. Feldhaus, L. Frazer, F. Freise, J. A. N. Friend, H. G. Graves, M. Gsell, A. de Gubernatis, W. Guertler, J. M. Heath, M. Hoernes, C. Hostmann, L. Jacob, A. von Kremer, I. E. Lester, F. von Luschan, J. V. McCartney, A. McWilliam, W. Maylor, H. B. Medlicott and W. T. Blanford, O. Montelius, D. Mushet, P. Neogi, H. Oldenburg, G. G. Pearse, G. Pearson, J. Percy, B. H. B. Powell, P. W. Powlett, P. C. Ray, L. Rousselet, A. Sahlin, O. Schrader, E. Schultze, C. von Schwarz, W. V. Scudamore, P. Sonnerat, W. Sowerby, M. Taylor, T. Turner, O. Vogel, J. Wallace, H. Wilkinson, K. Woermann, B. Yaneske, and F. X. M. Zippe —*vide infra*, the history of the blast furnace.

A knowledge of Indian steel must have filtered through from India to Ceylon ; and S. M. Burrows said that Wijiya was a petty prince in the valley of the Ganges, and that he, with his followers, landed in Ceylon in 543 B.C. The excavation of the buried cities of Ceylon, dating back to the fifth century B.C., has furnished a number of samples of iron, and A. K. Coomaraswamy, and H. Parker have described ancient processes of manufacturing iron, as well as various specimens of ancient iron and steel. H. le Chatelier raised the question whether the troostite found by R. A. Hadfield in an ancient chisel represented martensite which had been transformed by spontaneous annealing during the 1500 years the specimen had been in existence. R. A. Hadfield gave the following analyses of specimens of Sigiriya iron and steel of the fifth century :

	C	Si	S	P	Cu	Mn	Sp. gr.
Chisel . .	trace	0·12	0·003	0·28	0·090	nil	7·69
Nail . .	,,	0·11	Nil	0·32	0·119	nil	7·69
Ketta (axe) .	,,	0·26	0·22	0·34	0·012	trace	7·50

The use and manufacture of iron in Ceylon were discussed by J. Davy, R. A. Hadfield, H. Parker, L. K. Schmarda, and C. P. Thunberg. W. Rosenhain examined the links of a chain which had probably been exposed in Ceylon to the atmosphere for 2000 years. The relation of the Gipsies to the iron industry was discussed by R. Andrée, H. M. G. Grellmann, and J. Simson. The use and manufacture of iron in the East Indies and vicinity were discussed by F. de Magalhaes (Magellan), P. Sonnerat, J. Crawfurd, T. Waitz, J. B. van Hasselt, M. Schulze, H. Everett, J. Moura, H. Meyer, R. Andrée, A. Schadenberg, and W. Foy ; in Sumatra, by W. Marsden, L. Horner, R. Andrée, M. Moszkowsky ; in Java, by T. S. Raffles ; in Borneo, by G. W. Earl, C. A. L. M. Schwaner, and C. Hose and W. McDougall ; in Papua, by G. W. Earl ; in Malay, by H. von Rosenberg ; in Philippines, by A. Schadenberg ; and in Polynesia, by M. Hoernes.

G. F. Zimmer said that the Chinese used iron from the time of Emperor Fo-Hi, about 2000 B.C. At that time the aborigines of Tibet, the Miao-Tze, had iron swords and hatchets, and the Emperor Fo-Hi received tribute in supplies of iron from them. This period is probably less remote than is here indicated, for F. R. Tegengren said that the earliest period of the use of iron in China is in 722 B.C., and in 685 B.C. copper was still being used for swords and spears, whilst hoes and hatchets were made of iron. According to W. Ridgeway, the use of iron is mentioned in the *Yü Kung* dating from 2200 B.C. ; according to R. A. Smith, the province of Shan Si, in China, has yielded iron from remote times ; and, according to F. Hirth, iron was used in China for agricultural purposes in 696 B.C. Pliny, in his *Historia naturalis* (**34**. 41), said that the best iron was made by the Seres, and this is taken to have meant the Chinese. In the thirteenth century, Marco Polo referred to the use of iron by the Chinese, and M. A. Stein found evidence of the use of iron during the eighth and ninth centuries. The use and manufacture of iron in China were discussed by W. H. Adolph, R. Andrée, E. von Bibra, J. C. Brown, G. Chamier, M. Cremer, St. J. V. Day, F. A. Foster, F. Freise, W. Grube, M. Gsell, F. Hirth, M. Hoernes, J. Klaproth, E. Kocher, A. Ledebur,

J. Legge, F. Lenormant, E. O. von Lippmann, F. Lux, J. Markham, W. Matschoss, A. B. Middleton, O. Montelius, T. D. Morgan, M. Much, A. Pfizmaier, O. Rammstedt, T. T. Read, L. Richard, F. von Richthofen, B. Simmersbach, M. A. Stein, O. Stoll, C. P. Thunberg, O. Vogel, K. Wendt, E. Wiedemann, K. Woermann, and C. Yang and C. F. Wang.

According to W. Gowland, in Japan there were skilful workers of iron in the third or fourth century B.C. The swords are said to be " splendid examples of the work of the smith." E. Treptoff said that the oldest iron manufactured in Japan was at Sugaya in A.D. 1264. The use and manufacture of iron in Japan were discussed by R. Andrée, E. Baelz, B. H. Brough, St. J. V. Day, W. Dönitz, H. Fey, H. H. Manchester, C. P. Thunberg, and E. Treptoff ; and in Siberia, and Northern Asia, by R. Andrée, L. Cohn, M. Ebert, A. Erman, J. G. Gmelin, J. G. Georgi, B. F. J. Hermann, A. Kohn, S. Krascheninnikoff, A. Ledebur, A. von Middendorff, J. G. Müller, K. von Neumann, K. Nishio, A. E. von Nordenskjöld, P. S. Pallas, J. S. Poljäkoff, M. Radloff, J. Sievers, G. W. Steller, and E. Treptoff.

According to O. Montelius, the iron age commenced in Greece about 1500 B.C., and M. I. Rostovtzeff supposed that the iron industry was introduced by the Achæans into Greece between 1150 and 1200 B.C. The cube of iron found in 1927 at Knossos, in a Middle Minoan grave, dating from about 1800 B.C., was considered by H. R. Hall to be the " most ancient known worked iron from the Ægean area." Here again the specimen was considered as a precious metal, and is more likely to have been of meteoric origin. A similar remark also applies to the finger rings, date about 1550 B.C., found in the tombs at Pylos in the Peloponnese. J. L. Myres thinks that Herodotus may have been right in using the term *sigyunæ* for the throwing spears made wholly of iron which characterized the Iron Age culture of Cyprus in early Hellenic times. Homer, who flourished 880 B.C., was familiar with the metal ; and the Homeric Age, the period on which the *Iliad* and *Odyssey* are founded, ranges from 1400 to 1200 B.C. Both poems contain a few references to iron, and they may be taken to indicate what Homer himself thought of the use of this metal in the years to which reference is made. They prove little else. The subject was discussed by T. W. Allen, J. A. N. Friend, W. Helbig, A. Lang, V. Berard, W. Ridgeway, and H. B. Cotterill, and a collection of references is given by L. Beck—*vide infra*, the tempering of steel.

Iron was apparently on trial in Homer's time ; the Homeric swords, spears, and armour were generally of bronze, probably because, owing to poor methods of manufacture, the iron or steel weapons were unreliable and at a critical time might buckle or bend. Pausanias, in his *Periegesis* (**3.** 3, 6), in the 2nd century of our era, said that the weapons of the heroic age of Greece—*e.g.* the spear of Achilles, and the sword of Memnon—preserved in the Greek temples, were made of bronze. Iron does not appear to have replaced bronze in the manufacture of weapons of war until the sixth century B.C. L. Beck gives a number of references to iron in the *Theogony* of Hesiod, who flourished about 700 B.C. The *History* of Herodotus, written about 450 B.C., contains many references to the use of iron in Greece, Egypt, and the Near East. There are other references in Greek literature. Thus, Æschylus, in his *Prometheus* (**4.** 302 ; **6.** 712), called the Caucasus the " motherland of iron," and he praised the iron of the Chalybeans, located at the head of the Euphrates. The Greek term χάλυψ for steel takes its origin from these people. He also added that the Chalybean iron-workers are wild and inhospitable ; while Xenophon, in his *Anabasis* (**5.** 5), said that the whole race lived on the proceeds from the iron industry. E. O. von Lippmann also discussed the references to iron by Aristotle, who flourished between 384 B.C. and 322 B.C., and said :

Iron is obtained in large quantities from the ironstone of Elba and from the mines of the Chalybeans near Amisus, on the southern shore of the Black Sea. The ore is difficult to melt on account of the quantity of clay contained in it, and it is to be softened only by

raising it to a great heat. Iron is of great strength and very hard, though it is said that in Cyprus there are mice which are able to gnaw it. The best and hardest of all kinds of iron known is that of the Chalybeans, that is, steel (Chalybs), and it is obtained from iron by melting it repeatedly together with certain stones in a furnace, during which process much slag is formed and a great loss in weight occurs, on account of which the product is very costly. The finished steel is hard, with a glittering surface, and resists rust ; but it is not applicable to all the purposes for which less pure iron is used. The quality is judged by the sound given out in working it on the anvil. A Sicilian trader, recognizing that iron was an indispensable commodity, once succeeded in buying up the produce of all the smelters of iron, and made a profit of 200 per cent. when a scarcity arose.

In 1871, H. Schliemann began a series of investigations at Hissarlik, the site of ancient Troy, and found the remains of several cities, possibly nine, one super-posed above the other. The sixth turned out to be the Troy of Homer, dating from 1500 B.C., whilst the second dated back to 2500 B.C. From Troy, H. Schlie-mann went to Mycenæ, Greece, and there he discovered evidence of a civilization contemporaneous with that of the Homeric Troy. Excavations in Crete showed that the inhabitants there attained a high stage of civilization, which reached a zenith and then passed into oblivion. The Mycenæan civilization was derived from that of Crete. J. Evans found at Knossos buried cities with indications of a bronze age above neolithic remains, and he called it the *Minoan Age*, in allusion to Minos, the legendary sea-king of Crete, mentioned in Homer's *Odyssey*. Crete was then the dominant sea-power in the Mediterranean, and this period extended from about 4000 to 1200 B.C. There was now a transitional period when iron weapons, etc., began to accompany the bronze relics. The earliest iron weapons have been found in Eastern Crete, and then they appeared in Thessaly, and later still in Athens and Tiryns. Iron swords have been here found in graves dating from 1000 B.C. The history of iron in Greece was discussed by J. Beckmann, G. Beloch, H. Blümner, H. A. Boyd, R. M. Burrows, H. Chevalier, E. Curtius, F. M. Feldhaus, R. Forrer, F. Freise, L. Friedländer, M. Fuchs, M. Gercke, W. E. Gladstone, M. Gsell, H. Hanemann, M. Hoernes, J. Hoops, C. Hostmann, O. Immisch, O. Johannsen, O. Kern, C. Klinkenberg, A. Koerte, J. H. Krause, A. Lang, F. Lenormant, E. O. von Lippmann, C. A. von Lobeck, H. H. Manchester, A. H. Mauduit, E. Meyer, H. H. Montanus, O. Montelius, A. Macco, O. Olshausen, C. Pauli, K. Preisendanz, M. Regling, C. Robert, J. P. Rossignol, A. Rzach, O. Schrader, M. Sudhoff, K. Tümpel, M. Wessely, and S. Xanthoudides.

There was an advanced bronze age in Etruria, Italy, prior to 1000 B.C., and iron swords with bronze handles of this period are common in Etruscan remains. At the beginning of our era, Strabo, is his *Geographica* (**5.** 2), stated that iron ores were shipped from Elba for further treatment at Populonia (Piorubino)—the Sheffield of the Etruscan kingdom. The name *Elba* is said to be derived from the Greek ἔθειρα, in allusion to the flames of iron furnaces, and is said to indicate that when the Greeks discovered Elba, they found iron furnaces there at work. Virgil alluded to the inexhaustibility of the iron mines at Elba—*insula inexhaustis chalybium generoso metallis—Æneid* (**10.** 174)—and he added that the iron was so abundant that the soldiers sent from this neighbourhood to help Æneas were clad from head to foot in armour of iron. L. Simonin has described the remains of the bloomery hearths employed at Populonia for treating the ores from Elba. The Etruscan furnace was surrounded by blocks of sandstone, and the slag was well fused, honeycombed, black, and crystalline ; and it contained 40 per cent. of ferrous oxide. The charcoal seemed to have been derived from the oak and chestnut. The spoil-heap was over 600 yds. long, and about 7 ft. high. Diodorus Siculus also described the ironworks at Populonia. Some of the coins of ancient Populonia have the head of Vulcan with representations of hammer and tongs, thus showing the importance of the iron industry to the people there. Remains of an Etruscan ironworks have been discovered at Gheradessa on Mount Bucho al Ferro. The subject was discussed by A. Gurlt, H. Scott, and G. Dennis. T. Poech considered that the Elba mines date back to the time when iron first came

into general use. Some of the discoveries in the waste-heaps go back to the Stone Age, and the weapons with which Troy and Carthage were conquered were probably made from Elba ores. F. Odernheimer said that the Elba mines were known to the Phœnicians and were subsequently worked by the Greeks and Romans. Accurate data can be traced back to 1193 A.D., when the Emperor of Germany, Henry VI, transferred his mining rights over Elba to the Republic of Pisa.

The Romans displayed little inventive genius, and what successes they obtained in the arts and crafts were due to the work of imported craftsmen—1. 1, 29. There is a reference to the work in the smithy in Virgil's *Æneid* (8. 416) :

> As when the Cyclops, at th' Almighty nod,
> New thunder hasten for their angry god,
> Subdued in fire the stubborn metal lies ;
> One brawny smith the puffing bellows plies,
> And draws and blows reciprocating air :
> Others to quench the hissing mass prepare :
> With lifted arms they order every blow,
> And chime their sounding hammers in a row ;
> With laboured anvils Etna groans below.
> Strongly they strike ; huge flakes of flames expire :
> With tongs they turn the steel and vex it in the fire.

This shows that the Romans were familiar with steel and the method of tempering it prior to 30 B.C.—*vide infra*, the hardening of steel. There are also references to iron by other Roman poets—*e.g.* in Ovid's *Metamorphoses* (14. 712) ; in Horace's *Odes* (2. 16, 17, 51) ; and in Lucretius' *De rerum natura* (6. 148). Pliny, in his *Historia naturalis* (34. 39 to 45), *c.* A.D. 75, has collected the current lore concerning iron. He said that the art of working iron is due to Cyclops, and that other legends ascribe it to other sources. Pliny gave an account of the common types of iron ore, and the varieties of metal which they furnish. He attributed the effects of tempering (*q.v.*) to the nature of the water, and he said that the natural waters in some localities give better results than in others. He said that when the ore is fused, the metal becomes like water, and afterwards acquires a spongy, brittle texture. This is the way cast iron would behave. Pliny discussed the rusting of iron (*q.v.*), and the medicinal virtues of preparations of iron. He lamented the use of iron in the manufacture of weapons :

It is with iron that wars, murders, and robberies are effected, and this not only hand to hand, but from a distance even, by the aid of missiles and winged weapons, now launched from engines, now hurled by the human arm, and now furnished with feathery wings. This last I regard as the most criminal artifice that has been devised by the human mind ; for, as if to bring death upon man with still greater rapidity, we have given wings to iron and taught it to fly.

There are references by Diodorus, *Bibliotheca historica* (5. 33, 34), and by Livy, in his *Historia* (21. 8), to the use of iron in Spain. The history of iron in the Roman Empire and Italy was discusssed by L. Beck, J. Beckmann, H. Bell, H. Blümner, R. Forrer, F. Freise, C. Fremont, L. Friedländer, M. Gummerus, A. Gurlt, H. Hanemann, T. Haupt, J. F. L. Hausmann, M. Hoernes, J. Hoops, E. Hübner, H. Jentsch, W. Kroll, A. Ledebur, R. Marggraff, H. H. Manchester, C. Mehlis, E. Meyer, S. Mockrauer, O. Montelius, A. Morlot, B. Neumann, E. Riess, J. P. Rossignol, H. Rupe, M. Sagey, O. Schrader, H. Scott, M. Skutsch, O. Stoll, R. von Stoltzenberg, P. C. J. B. Tronson du Coudray, F. Winkelmann, and G. Wissowa.

According to R. von B. Baum, Punic and Roman tools have been found in old workings in North-West Africa, showing that there the iron-mining industry goes back to ancient times. The iron mines and the ferruginous gold of Bona are referred to by Leo Africanus. There was afterwards a period of decadence. Emir Abd-el-Kader recognized the importance of the iron-ore industry to Algiers, and the ore of Zaccar-Rharbi was there smelted in charcoal blast furnaces. According to L. Beck, the natives of Africa, Egypt excepted, extracted iron from its ores from a very remote period. The seats of the ancient iron industry are evidenced

by accumulations of slag and debris, and are widely distributed in that continent. W. Gowland, and L. Beck believe that the iron at the early period must have been indigenous in Africa. R. Dart reported some results of excavations in the Mumowa caves near Broken Hill, North Rhodesia. The remains of an old smelting furnace were taken to indicate that iron was there manufactured 3000 to 4000 years ago—2070 B.C.—by a people of palæolithic culture dwelling in Central Africa. T. A. Rickard considered this to be very improbable, and that the remains are really those of foreigners versed in iron-making who established themselves for defensive purposes in the caves and made iron weapons for use against the natives.

The idea, advocated by W. E. B. du Bois, that the discovery of iron originated amongst the African negroes, and that the Egyptians acquired the art from their Ethiopian neighbours to the south or from their Libyan neighbours to the west of the Nile valley, is not probable, because the available evidence shows that the civilizations of Ethiopia and Nubia always lagged behind that of Egypt. Herodotus (**2.** 124) observed that :

The Ethiopian contingent of Xerxes' army was armed with long bows, on which they placed short arrows made of cane, not tipped with iron, but with stone which was made sharp, and of the kind with which we engrave seals. Besides these they had javelins, tipped with antelope's horn that had been made sharp like a lance. They also had knotted clubs.

H. Balfour thus summarized F. von Luschan's arguments in favour of the African negro as the originator of the method for extracting iron from its ores :

(1) That the high antiquity of iron-working among Negro and Bantu tribes is evidenced by its very widespread dispersal among them, and by the great degree of skill acquired by the native smiths. (2) That iron ores are very abundant in Africa, and can be collected with ease on or near the surface. (3) That some of these ores are easily reducible at a relatively low temperature, and can be, in fact, reduced in an ordinary fire. (4) That in Karagwé, Kordofan, and Usindja may be seen such open fires still used for iron smelting, and there are variations in this simple procedure which suggest stages in the evolution from the open fire to the closed kiln. If iron smelting had been introduced to the negro by an exotic people who had already considerably advanced the industry, these crude and seemingly prototypical methods would not have been adopted in the region ; and that evidence for the early stages in the progression from simple to complex should be sought for elsewhere, not in savage Africa, where, however, they seem to obtrude themselves.

It is quite possible, even probable, that the method of extracting iron from its ores was independently discovered in several different localities—say, the Caspian area, in Central Africa, etc.—and that the quest for a very first discoverer is illusive.

Diodorus (**3.** 13) said that the chisels used in the mining of gold in Nubia for the old Egyptian kings were made of *latomides chalkai*—*i.e.* copper or bronze—because iron was then unknown. W. M. F. Petrie and co-workers, L. W. King and H. R. Hall, and H. R. Hall do not consider it probable that the early Egyptian iron was obtained by trade from outside sources—*e.g.* the Nubians and negroes—although in the opinion of G. A. Wainwright, the art of working iron entered Egypt from Asia, and thence passed by other parts of Africa.

The use and manufacture of iron in Africa were discussed by R. Andrée, B. Ankermann, C. Arendt, J. Backhouse, S. W. Baker, H. Barth, C. V. Bellamy, J. T. Brent, T. E. Bowdich, A. E. Brahm, R. F. Burton, R. Caillié, V. L. Cameron, P. B. du Chaillu, C. C. von der Decken, A. Delegorgue, F. Dixey, J. L. Döhne, E. Dulaurier, K. Endemann, J. R. Evans, G. Fritsch, E. de Froberville, M. Guillain, W. von Harnier, M. T. von Heuglin, M. Hoernes, J. E. Holgate, E. Holub, F. Hupfeld, T. J. Hutchinson, M. Kranz, A. Lambert, J. T. Last, O. Lenz, D. Livingstone, F. von Luschan, L. Magyar, A. Mansfield, G. H. Mason, A. F. Mockler-Ferryman, G. Mollien, J. M. C. Monteiro, G. Nachtigal, S. Passarge, P. Paulitschke, J. Petherick, S. Pinto, P. Pogge, A. F. Pott, A. F. Prévost, S. Purchas, A. Raffenel, T. A. Rickard, G. Rohlfs, J. Russegger, C. Schefer, O. Schrader, O. H. Schütt, G. Schweinfurth, H. M. Stanley, P. Staudinger, G. Tessmann, J. Thomson, F. le Vaillant, T. Waitz, M. Weiss, K. Weule, and C. T. Wilson and R. W. Felkin—*vide infra*, the history of the blast furnace. The use of iron in Madagascar was discussed by W. Ellis, and G. P. Chaplin.

The cemeteries of Hallstadt, in the Austrian Tyrol, and of La Tène, in Switzerland,

have furnished materials which have enabled archæologists to trace a gradual growth in culture through the bronze age to the iron age over a period from about 850 to 1 B.C. M. I. Rostovtzeff believed that the iron age in the Caspian area of the Near East dates back to 1400 B.C.; and that the Achæans arrived in Greece with a well-developed iron industry about 1200 to 1150 B.C. Hence, inquires H. Balfour :

Why is it that in the Hallstadt culture of Central Europe, which is generally considered to go back to about 850 B.C., there is unmistakable evidence of a gradual transition from bronze to iron ? Is the initiation of the iron age in Central Europe independent of its inauguration in the Near East and among the Achæans ? Or did a rudimentary knowledge of the use of iron spread westward without acquaintance with the improved types of implements and developed technique which had already been evolved farther to the east ? Or does the dating require reconsideration ?

W. Ridgeway was so impressed with the traces of the old iron industry at Hallstadt that he believed the use of iron as a metal began in Central Europe, not in Egypt or, indeed, Africa. According to V. Gross, iron was smelted near Hallstadt, Austria, and in the Bernese Jura from 2000 B.C. This subject was discussed by O. Montelius, O. Schrader, R. Forrer, M. Gsell, M. Hoernes, H. Rupe and F. Müller, O. Johannsen, J. Pokorny, J. Hoops, F. M. Feldhaus, J. Beckmann, A. Schulten, F. Freise, H. Blümner, K. Tanzer, R. Munro, H. J. E. Peake, A. Müllner, A. Quiquerez, and E. von Sacken. H. Hanemann analyzed and examined microscopically samples of iron of the La Tène period, about 500 B.C. Noricum (Noreia) —embracing Carinthia, and Styria, Görz, and Istria, in the Austrian Tyrol—-was one of the 'earliest centres of the iron industry in Europe. It is alluded to by G. Jars, who visited Erzberg in 1758. Both Horace, in his *Epodon* (**17.** 71) and in his *Odes* (**1.** 16), and Ovid, in his *Metamorphoses* (**14.** 712), refer to the high quality of *Noric iron*. A. Macco said the iron in the neighbourhood of Krivoi Rog, Russia, was used by the ancient Greeks ; and that it is probable that the famed *Scythian iron* came from this neighbourhood.

According to R. Forrer, and J. Hoops, iron was known in Sweden 800 B.C., and, according to O. Montelius, O. Schrader, J. Hoops, J. Schlemm, and W. Tomaschek, the iron age began there about 500 B.C. There are numerous references to iron weapons and utensils in the sagas of the vikings and gods of Scandinavia and Iceland during the period between A.D. 800 and A.D. 1100— W. von Gravenberch, K. Simrock, etc. M. Wahlberg said that it is known with certainty that iron began to be manufactured in Sweden at least 500 B.C., and for about 2000 years afterwards malleable iron was produced directly from the ore— chiefly bog iron ore. The vikings were probably able to produce iron objects of large size ; thus, the iron anchor of a ship was found in a barrow of Oseberg, Sem, and described by G. Gustafson. The vikings do not appear to have had control of the method of making a thin strip of metal, like a sword, which would retain a cutting edge and not bend. This remark applies to many of the ancient iron-workers in other lands ; so that when the smith did succeed in producing a satis-factory weapon the event was celebrated in saga and legend where the fame of a sword with its own special name was recorded. D. Livingstone and others have mentioned the frequency with which the spears of the natives of Africa were bent when in use. V. Schmidt discussed the occurrence of prehistoric iron in Denmark —for Germany, etc., *vide infra*.

The inhabitants of Britain were acquainted with iron at least two centuries before our era. According to R. A. Smith :

Although there are various proofs that iron was produced in Britain centuries before the Roman occupation, no furnaces of the earliest period have been discovered ; and it is therefore probable that the ancient Britons employed the simple low hearth, resembling the Catalan furnace of the Pyrenees, which has been in use there from very remote times to our own day. The source from which Britain derived the furnace and art of extracting iron from its ore seems to have been the Mediterranean region, either the eastern Pyrenees or north-west Italy ; but it may also be reasonably held that the first iron-furnace of the Britons was derived from that used so successfully in the extraction of tin. It is important

to notice that two of the earliest sites of ironworks in Europe are situated in the Upper Danubian region, within easy reach of the famous cemetery of Hallstadt. One is in the neighbourhood of Hüttenberg, in the upper basin of the Drave, Carinthia ; the second on another tributary of the Danube, the Mur in Styria.

Julius Cæsar, in his *De bello gallico*, mentioned that when he arrived, the Britons used brass or iron rings, determined at a certain weight, as money ; and that iron was produced in the maritime regions. Currency bars have been found at Maidenhead (Berkshire) ; Minety (Wiltshire) ; Wookey Hole, Glastonbury, and Ham Hill or Hamdon (Somerset) ; Winchester (Hampshire) ; Meon Hill and Bourton-on-the-Water (Gloucestershire) ; Malvern and Littleton (Worcestershire) ; Hunsbury (Northamptonshire) ; Ventnor (Isle of Wight) ; Hod Hill and Spettisbury (Dorset) ; and Holne Chase (Devonshire). The subject was discussed by R. A. Smith, A. Lane-Fox, J. W. Hall, T. S. Ashton, R. Jenkins, J. H. Evesy, R. Baker, C. W. von Siemens, T. Turner, H. Louis, C. Dawson, J. Lewis, H. Gaythorpe, M. S. Giuseppi, W. P. Breach, H. C. Evans, T. Vickers, W. C. Symons, and J. Evans. Analyses were reported by B. H. Brough, J. Myers, and W. Gowland. According to Julius Cæsar, the Britons at the time of the Roman conquest were famous for chariots of war drawn by two horses abreast, with a pole between them. The object was to maim the enemy. When a chief died, the chariot and its equipment were sometimes buried with him. Fragments of the iron rims of the wheels of some of these chariots have been found—*e.g.* in the East Riding of Yorkshire. The wheels were in some cases 3 ft. in diameter. There is no satisfactory evidence of the use of scythed chariots. J. R. Mortimer found numerous relics of an early iron age in the burial mounds in the district between York and Bridlington. T. May described an iron-smelting furnace of the Roman period at Wilderspool and Stockton Heath, near Warrington. The furnace consisted of a wall covered with clay, and there were holes at the base for letting in air and allowing the metal to run out. For this purpose, also, the furnaces were usually placed on sloping ground. Rude bellows may have been used. C. Wilkins seems to consider that South Wales was the original home of the iron trade of Britain. In Roman times extensive ironworks developed in Gloucestershire. The iron relics of early man in Britain found at Wookey Hole, near Wells, Somerset, were described by H. E. Balch ; they include brooches, currency bars, a sickle, an ox-shoe, a dagger, etc. A. Bulleid and H. St. G. Gray described the relics found at works at Glastonbury (A.D. 120). Emperor Hadrian established a works at Bath, where iron from the Forest of Dean was worked. G. Payne gave an account of the iron industry which prevailed in the Weald of Kent in the sixteenth century. There were furnaces, forges, or foundries at Cowden, Hawkhurst, Lamberhurst, Cranbrook, Goudhurst, Domdale, Hormoden, Tonbridge, and Biddenden. There was a rapid decline in the seventeenth century, so that in 1796 not one furnace was at work in Kent. According to S. H. Hollands, the last ironworks in the Weald of Sussex were at Ashburnham, and they were dismantled in 1828. Some of the present names of places recall the old industry—*e.g.* Hammer Ponds. The subject was also discussed by M. A. Lower, and E. Straker. In 1673, J. Smith described the condition of the iron trade of Sussex at that time, and fears were expressed as to the extinction of the forests to supply fuel for the 130 hammers and furnaces then in use. F. Cartwright gave an account of the history of iron in Sussex—*vide infra*. Excavations have been made near Richborough Castle, in the vicinity of Sandwich, Kent, which was once the site of a Roman naval station known as Rutupiæ. Many iron relics, including brooches, bangles, rings, nails, and the iron head of an axe, were unearthed. Analyses of two iron nails have been made by J. A. N. Friend and W. E. Thorneycroft. One nail contained 0·080 per cent. of carbon and 0·046 of sulphur, no manganese, and a trace of phosphorus ; another nail had 0·070 per cent. of carbon, and no manganese, phosphorus, or sulphur. East Cliff, Folkestone, has also been identified as a Roman site, and excavations, described by S. E. Wibolt, have revealed a number of iron implements of various kinds. Some of them

were described by J. A. N. Friend and W. E. Thorneycroft. The iron relics found at Uriconium, near Wroxeter, Shropshire, have been described by J. P. Bushe-Fox. The Roman iron found at Corstopitum, on the north bank of the River Tyne, was described by H. Bell, F. Haverfield, G. Turner, R. H. Forster, and W. H. Knowles. J. E. Stead gave for the analysis of the bloom : 0·097, C ; 0·046, Si ; 0·025, S ; 0·044, P ; 0·049, As ; 0·010, Cu ; 0·040, Mn ; and 0·380, cinder. H. Louis concluded that the Romans smelted the little balls of iron with charcoal, at or near the outcrop of the local ores, and transported the cakes of spongy iron so obtained to the town of Corstopitum to be worked up into articles of various kinds. W. G. Collingwood and H. S. Cooper described the ancient bloomery at Coniston ; and G. T. Lapsley described the account roll of a fifteenth-century ironmaster in Weardale—*vide infra*. Small iron bloomery furnaces were erected at Pontypool, South Wales, in 1425 ; and in the sixteenth century the old Sussex ironmasters, owing to restrictive measures, migrated to South Wales and established the iron industry there. About 1577 the Lansdown MSS. says that Richard Hanbury had "gott to his handes ij or iij iron workes there in Wales, whereat he made much merchant iron to greate gaine." This subject was discussed by W. Coxe, W. Llewellyn, and D. Griffiths.

According to G. F. Zimmer, and J. Lubbock, Amerigo Vespucci, who journeyed to America between 1497 and 1504, and after whom America was named, stated that when he first went to the La Plata region of South America, he found that the Indians made arrow-heads and other implements out of bits of iron derived from masses that had fallen from the sky. This is the only reference to iron occurring in the description by Amerigo Vespucci of his four voyages between 1497 and 1504 :

Their (Indians) arms are bows and arrows, very well made, save that (the arrows) are not (tipped) with iron nor any other kind of hard metal, and instead of iron they put animals or fishes teeth or a spike of tough wood, with the point hardened by fire.

E. B. Tylor said that the Mexicans were familiar with iron at the time of the Spanish Conquest, and that they first called their copper and bronze *tepuztli* ; the same word was employed as a general term for metal, and it was also applied to iron. In order to distinguish the two metals, copper was called *red tepuztli*, and iron, *black tepuztli*.

According to F. W. Putnam, the relics of the mound-builders of the Mississippi valley include gold, silver, and copper ornaments—beads, buttons, and bracelets —made from native metals by hammering ; and meteoric iron was fashioned into beads, adzes, and chisels in the same way. The mound in the Turner group of Ohio contained a piece of meteoric iron in its natural state and another piece which had been flattened by hammering. G. F. Kunz showed that some specimens of meteoric iron can be shaped by hammering with stone ; the Otumpa meteorite, found in Argentine, has scars indicating where pieces have been detached ; the Descubridora meteorite, in Mexico, has a gap in which is wedged a broken copper chisel left there by a primitive worker; and the Catorze meteorite, in Mexico, likewise had a chisel of native copper wedged in a cavity in the meteorite. W. H. Prescott pointed out that although the nations of Peru were unacquainted with iron, they had acquired the art of cutting the hardest substances, like emeralds, with tools of stone and copper ; similarly also with the natives of Mexico, who used instruments of copper, with an alloy of tin, and a siliceous powder for cutting the hardest stones. On the other hand, as pointed out by G. F. Zimmer, H. Hensoldt has said :

When Cortez had completed the conquest of Mexico the Spaniards, among a great many other peculiar and extraordinary observations which they made in that remarkable country, were particularly struck and puzzled by one fact. They noticed that the Aztecs possessed certain implements, such as knives, daggers, etc., made of iron, but it seemed that only the most distinguished of the natives possessed such, that iron was a great rarity and was prized higher than gold. At first the Spaniards believed that the Aztecs extracted the

metal in some crude fashion from its ore, which abounds in many parts of the country, but they soon ascertained that this was not the case. They found that not a single smelting furnace existed in the empire, and their surprise was not small when they learned that the Aztecs were totally unacquainted with any method of extracting the iron from the ore, which, indeed, they had never suspected of any kinship with the highly valued metal. The question whence the Aztecs had procured the little iron they possessed became a perplexing problem to the Spaniards, which they were never able to solve. The natives do not seem to have enlightened them much on the subject, for when asked they mysteriously pointed to the sky, and indicated that they obtained their iron from the regions above. Such assertions, no doubt, the Spaniards received with an incredulous smile, and they concluded that the Aztecs procured it by way of traffic with some other, perhaps more civilized, nation which they suspected to exist and kept looking for north and south for more than a hundred years. The Aztecs were quite correct ; the iron of which they had made their implements was not fashioned from materials of this terrestrial globe, but had come to them from the unknown regions of space. Their iron was, in fact, of meteoric origin, like that of the Mayas of Yucatan and the Incas of Peru, of which many weapons are still preserved in collections.

The use and manufacture of iron in America before the so-called discovery of that country by Columbus were discussed by J. de Acosta, R. Andrée, A. Bastian, L. Beck, A. de Herrera, H. Hoerens, C. Hostmann, W. H. Holmes, F. de Magalhaes (Magellan), H. H. Manchester, G. C. Musters, J. A. F. le Marquis de Nadaillac, W. H. Prescott, W. Rhaleg, T. A. Rickard, and R. Virchow—*vide infra.*

There are bibliographies of the more recent developments of the iron and steel industries [2]—Great Britain,[3] France,[4] Belgium,[5] Alsace-Lorraine and Luxemburg,[6] and Sweden.[7] According to L. Beck, in 1240, Philippus domus de Florenges gave to the monks of the Abbey of Villers-Bettnach the right to mine iron ores in his lands ; and in 1260, Thierry, Lord of Hagingen (Haeges), gave to Count Theobald von Bar the right to mine the iron in his forests of Briey. In 1323, a forge served by water-power was erected near Moyeuvre. In 1490, an ironworks was erected at Ars-on-the-Moselle, and from these early dates the evolution of the iron industry in this region has continued up to the present time. In Tacitus' *Germania,* written in the first century of our era, there are references to the use or manufacture of iron in Germany ; and, according to O. Schrader,[8] the Germans learned the use of iron in the fourth century B.C. from the Celts. The early manufacture of the metal in Germany was described by L. Beck, L. Lindenschmit, M. Schulz, I. Undset, etc. Writings on the subsequent period are very numerous. In 1758, J. G. Lehmann described some iron mines in Prussia and said that in abandoned mines the iron ore grows again, so that in a few years new ore appears, but not of such good quality as the original ore. O. Krasa observed the remains of the smelting hearths of old Celtic ironworks at Rittershausen dating back to 1000 B.C.

In connection with the development of the iron and steel industries in Finland,[9] O. Schrader reported that the West Finns owe their acquaintance with iron to the Germans, and the East Finns, to the Iranians. The development of iron and steel has been studied in connection with other countries—Russia,[10] the Balkan States,[11] the old Austria-Hungary,[12] Switzerland,[13] Italy,[14] Spain and Portugal,[15] Australia,[16] New Zealand,[17] India,[18] Japan,[19] the United States,[20] Canada,[21] Cuba,[22] Brazil,[23] and Chili.[24]

In olden times iron was symbolized by ♂, the spear and shield of Mars, the God of War, probably in allusion to its use in making weapons of war. The term *Mars* for iron was in common use amongst the alchemists, and it survives in such terms as *crocus martis,* employed still in some of the older industries. The following is R. Russell's [25] translation from the twelfth-century work, *Summa perfectionis magisterii,* of Geber, and it gives some idea of the style of the writings of the period :

But the *Declaration* of *Mars,* and the whole *Secret* thereof, is from the *Work* of *Nature*: because it is a *Metallick Body,* very livid, a little red, pertaking of *Whiteness,* not pure, sustaining *Ignition,* fusible with no right fusion, under the *Hammer* extensible, and sounding much. But *Mars,* is hard to be handled, by reason of the *Impotency* of its fusion, which if it be made to flow by a *Medicine* changing its *Nature,* is conjoyned to *Sol* and *Luna,* and

not separated by *Examen*, without great *Industry*, but if prepared, it is conjoyned, and not separated by any *Artifice*, if the Nature of that *Fixation* be not changed by it, the Unclean-ness only of the *Mars* being removed : Therefore it is a *Tincture* of *Redness* easily, but difficultly of *Whiteness*. And when it is conjoyned, it is not altered, nor doth it change the *Colour* of the *Commixtion*, but augments it in *Quantity*.

E. Wiedemann gave an account of the Arabian writer Ibn Hudail, who lived at the beginning of the eleventh century. The Arabian said that iron exists in two modifications—male and female. Steel is the male variety, soft iron the female. J. de Hammer-Purgstall, and E. Rödigfr wrote on this subject. According to J. J. Becher's *tria prima* theory—**1.** 1, 15—iron was a compound of three primitives, so that when iron appears in the ash of certain substances, it was not originally present as iron, but the iron has been synthesized, so to speak, by a readjustment of the three primitives. E. F. Geoffroy favoured the same hypothesis, but L. Lemery showed that it is very improbable. Then followed the phlogiston hypo-thesis, which was discarded with the advent of A. L. Lavoisier's *Traité élémentaire de chimie* (Paris, 1789), and iron came to be generally recognized as an elemental form of matter. The history of the various forms of iron associated with carbon —cast iron, steel, etc.—is outlined later on.

J. K. F. Meyer [26] reported, in 1780, that crude iron contained a new element—named *hydrosiderum*—which remained as a residue when the metal was dissolved in acid. M. H. Klaproth showed that the alleged element is a compound of iron and phosphorus. A similar remark applies to the *siderum* found by T. Bergman in cold short iron. G. G. Boucher thought that he had discovered a new element in the dust of a blast furnace. F. G. Ruddock confirmed this, but C. H. Jones showed that the alleged reactions correspond with those of molybdenum. J. P. Prat also reported a new element in pyrite, and he called it *lavœsium*, but the report has not been confirmed.

General observations on or references to the history of iron have been made in numerous special books or memoirs. There are :

Sixteenth-century works : G. Agricola, *De re metallica*, Basileæ, 1561 ; P. Albinus, *Meyssnische Bergkchronica*, Dresden, 134, 590 ; V. Biringuccio, *De la pirotechnia*, Venezia, 1540 ; A. Cæsalpinus, *De metallicis*, Romæ, 1596 ; H. Cardanus, *De rerum varietate*, Basileæ, 1557 ; L. Ercker, *Beschreibung Allerfurnemisten mineralischen Ertzt unnd Bergkwercks Arten*, Franckfurt a. M., 1598 ; C. Gesner, *De omni rerum fossilium genere, gemmis, lapidibus, metallis*, Tiguri, 1565 ; J. Mathesius, *Sarepta oder Bergpostill*, Nürnberg, 1564 ; N. de Monardo, *Historia de les plantas que se traen de las Indias*, Serilla, 1580 ; S. Munster, *Cosmographia*, Basel, 1544.

Seventeenth-century works : A. A. Barba, *Arte de los Metales*, Madrid, 1640 ; D. Dudley, *Metallum martis*, London, 1665 ; London, 1851 ; T. Garzoni, *La Piazza universale di tutte le professioni del mondo*, Venetia, 98, 1610 ; J. R. Glauberus, *Operis mineralis*, Amstelodami, 29, 1659 ; G. E. Löhneyss, *Bericht vom Berkwerck*, Zellerfeldt, 1617 ; S. Purchas, *His Pilgrimes*, London, 1814, 1625 ; S. Sturtevant, *Metallica*, London, 1612.

Eighteenth-century works : M. Bazin, *Traité sur l'acier d'Alsace ou l'art de convertir le fer en fonte en acier*, Paris, 1737 ; T. Bergman, *De analysi ferri*, Upsala, 1781 ; W. Blakey, *Réflexions sur les progrès de la fabrique de fer et de l'acier dans la Grande-Bretagne*, Londres, 1783 ; G. L. L. de Buffon, *Histoire des minéraux*, Paris, **2.** 341, 1783 ; B. Caryophilus, *De antiquis auri, argenti, stanni, œris, ferri, plumbique fodinis*, Viennæ, 1757 ; G. le Courtivron and E. J. Boucher, *Art des forges et fourneaux à fer*, Paris, 1762 ; F. B. de Félice, *Forges du art de fer*, Yverdan, 1777 ; J. J. Ferber, *Physikalisch-metallurgische Abhandlungen über die Gebirge und Berwerke in Ungarn, nebst Beschreibung des steirischen Eisenschmelzens und Stahlmachens*, Berlin, 1780 ; *Mineralogische und metallurgische Bemerkungen in Neuchâtel*, Berlin, 1789 ; F. A. C. Gren, *Systematisches Handbuch der gesammten Chemie*, Halle, 434, 1795 ; P. C. Grignon, *Mémoires de physique sur l'art de fabriquer le fer*, Paris, 1775 ; B. F. J. von Herrmann, *Crell's Ann. Beyträge*, **5.** 274, 373, 1791 ; **6.** 3, 1799 ; G. Herwig, *Briefe über die Bergkunde, über Eisengruben und Rohschmelzen*, Frankfurt a. M., 1789 ; *Vier Abhandlungen über Gegenstände der Bergbaukunde und Kammeralwissenschaft*, Frank-furt, 1792 ; J. von Hofmann, *Abhandlung über die Eisenhütten*, Hof, 1783 ; *Crell's Ann.*, i. 564. 1785 ; H. Horne, *Essays concerning Iron and Steel*, London, 1773 ; G. Jars, *Voyages métallurgiques*, Lyon, 1774 ; C. Linnæus, *Pluto Svecicus* (MS.), Stockholm, 1734 ; C. A. von der Monde, C. L. Berthollet and G. Monge, *Hist. Acad.*, Paris, 132, 1786 ; J. B. G. de Morveau, *Rapport sur les résultats des expériences de Clouet sur les différents états du fer pour la conversion du fer en acier fondu*, Paris, 1898 ; M. Ostmann, *Crell's Ann. Beyträge*, **6.** 194, 1799 ; C. Polhem (Polhammer), *Patriotisches Testament*, Stockholm, 1761 ; R. A. F. de Réaumur, *L'art de convertir le fer forgé en acier*, Paris, 1722 ; *An Essay on the Mystery of Steel*, London, 1771 ; G. Rinman, *Academisk Afhandling om Jernets Tilwarknings*, Upsala,

1782; *Crell's Ann.*, ii, 469, 1784; S. Rinman, *Anledninger til Kunskap om den gröfre Jern-och Stål-Förädlingen och des Forbättrande*, Stockholm, 1772; *Försck till Järnets, Historia, med Tillämyning för Slögder och Handtwerk*, Stockholm, 1782; Berlin, 1785; G. F. Rippentrop, *Crell's Ann.*, ii, 411, 506, 1796; B. F. Rothoff, *Academisk Afhandling i svenska Bergs-Lagfarenheten om författninger, rörande fkogarnas värd och nyttjande til bergwerkens tjenst*, Upsala, 1778; *Crell's Ann.*, ii, 467, 1784; P. Saxholm, *De ferro succecano osmund*, Upsaliæ, 1725; J. G. Schneider, *Analecta ad historiam rei metallicæ veterum*, Viadrum, 24, 1788; J. S. § 2. The Occurrence of Iron

> Gold is for the mistress, silver for the maid,
> Copper for the craftsman, cunning at his trade.
> " Good," said the Baron, sitting in his hall,
> " But iron—cold iron—is master of them all."—OLD TALE.

Metallic iron occurs free in nature, but it is comparatively rare. This might be anticipated on account of the readiness with which the metal is oxidized in moist air. Combined iron is exceedingly common, occurring as it does in hundreds of minerals—oxides, hydrated oxides, carbonates, silicates, sulphides, etc. It occurs frequently in smaller proportions in various rocks, particularly those containing amphiboles, pyroxenes, micas, and olivine. It is so common, indeed, that an extraordinary number of rocks and minerals owe their tints—particularly when fired—to the presence of a small proportion of admixed iron compounds, and that R. J. Haüy [1] could say with truth that when Nature takes up her brush, iron oxide is almost always on her palette. W. Spring discussed the coloration of soils by ferruginous matter—*vide infra*, ferric oxide. C. M. Smyth discussed the abstraction of oxygen from the air by the iron in the earth's crust.

According to G. Tammann, the results of seismographic observations agree with the assumption that the earth's crust can be roughly divided into three layers, or rather, a core and two shells, namely :

	Thickness (Kilometres)	Density	Composition
Silicate layers	0 to 1500	2·9	$(Al_2O_3,Fe_2O_3,FeO,CaO,MgO, K_2O,Na_2O).1\cdot5SiO_2$
Sulphide layer	1500 to 2900	5·6	FeS,Fe_2P,FeO,Fe_2SiO_2
Metal core	2900 to 6370	9·6	Fe, 88 ; Ni, 8 ; (Fe : SP), 3 ; rare metals, 1 per cent.

According to F. W. Clarke, in the outer crust, iron ranks fourth in the list of

elements arranged in the order of their relative abundance in the earth's lithosphere. The order is : oxygen, 46·46 per cent.; silicon, 27·61 per cent.; aluminium, 8·07 per cent.; iron, 5·06 per cent.; and calcium, 3·64 per cent.; or, taking the average of the hydrosphere and lithosphere, O, 49·20 ; Si, 25·67 ; Al, 7·50 ; Fe, 4·71 ; and Ca, 3·39. Consequently, iron is outranked only by oxygen, silicon, and aluminium, and is closely followed by calcium—cf. Table I. For the average composition of the igneous rocks F. W. Clarke and H. S. Washington gave O, 46·59 ; Si, 27·72·; Al, 8·13 ; Fe, 5·01 ; and Ca, 3·63 ; whilst J. H. L. Vogt gave O, 47·2 ; Si, 28·0 ; Al, 8·00 ; Fe, 4·5 ; and Ca, 3·5 ; and W. Vernadsky, O, 49·7 ; Si, 26·0 ; Al, 7·45 ; Fe, 4·2 ; and Ca, 3·25. It is further supposed, from the density of the earth, that iron is much more abundant towards the centre of the globe, and that if estimates could be made for the whole earth, iron would occupy a more prominent position in the list. According to A. E. Fersman, taking the atomic proportions, the order is O, 53·81 ; H, 17·18 ; Si, 15·85 ; Al, 4·76 ; Na, 1·80 ; Mg, 1·67 ; Ca, 1·44 ; Fe, 1·30 ; and K, 1·04 per cent. W. Lindgren estimated the relative natural abundance of some commercial metals, with gold unity, to be :

Al	Fe	Mn	Ni	Cu	Zn	Pb	Ag
15,680,000	8,800,000	16,000	46,000	15,000	8,000	4,000	20

Considering the oxidized elements, F. W. Clarke gave for the percentage composition of the lithophere :

	Igneous rocks	Shale	Sandstone	Limestone	Weighted Average
SiO_2	59·14	58·10	78·33	5·19	59·08
Al_2O_3	15·34	15·40	4·77	0·81	15·23
Fe_2O_3	3·08	4·02	1·07	0·54	3·10
FeO	3·80	2·45	0·30	—	3·72
CaO	5·08	3·11	1·16	42·57	5·10
MgO	3·49	2·44	5·50	7·89	5·10
Na_2O	3·84	1·30	0·45	0·05	3·71

W. and I. Noddack and O. Berg gave for the absolute abundance of the elements in the earth's crust : Fe, $4·7 \times 10^{-2}$; Co, $1·8 \times 10^{-6}$; Ni, $1·8 \times 10^{-5}$; and Cu, $1·0 \times 10^{-4}$. A. von Antropoff estimated the atomic percentage to be :

	Stellar atmospheres	Earth's crust	Whole earth	Silicate meteorites
Si	5·7	16·20	9·58	11·2
Na	5·7	2·02	0·97	0·6
Al	3·6	4·95	2·66	1·1
Fe	2·5	1·48	46·37	5·92
Mn	0·36	0·035	0·06	—

The subject was also discussed by V. M. Goldschmidt, E. Herlinger, O. Hahn, J. Joly, L. de Launay, F. W. Clarke, H. S. Washington, G. Berg, R. A. Sonder, R. Wildt, and P. Niggli.

The relative distributions of ferric and ferrous oxides in British and American igneous rocks are, according to A. Harker :

	Fe_2O_3	FeO
British igneous rocks	5·34	2·40
American igneous rocks	2·65	3·35

Iron occurs native as a terrestrial mineral, but it is so scarce and unimportant that it is regarded as a mineralogical curiosity. Minute grains of native iron occur in many eruptive rocks—particularly basalts. They were first demonstrated by T. Andrews [2] in the basalt of Antrim, Ireland. The iron gave a precipitate of copper when placed in a soln. of copper sulphate ; and A. von Lasaulx found that the particles of iron also reduce a soln. of cadmium borotungstate, producing violet-blue patches in the liquid. Several of the specimens of meteoric iron which have been discovered may be really of terrestrial origin. G. F. Zimmer has discussed the reports of S. Hearne, J. Ross, R. E. Peary, J. S. Steenstrup,

D. C. Clavering, and I. I. Hayes on the meteoric origin of the iron employed by the Eskimos for making arrow-heads, spear-heads, knives, etc. In 1870, A. E. Nordenskjöld discovered a remarkable deposit of iron at Ovifak, Disco Island, Greenland. In some cases masses of iron up to 20 tons in weight have weathered out like boulders from the basalt, and lenticular and disc-like pieces of metal, still uncorroded, were embedded in the mass. The iron was at first thought to be meteoric, but the evidence points the other way. The iron phosphide, schreibersite, common to many meteorites, is absent; J. S. Steenstrup showed that native iron is abundantly disseminated through the basalt of that region; A. Daubrée obtained pellets of iron by fusing a native chrome spinel with carbon, and he showed that beds of lignite occur on the island, and graphite is associated with native iron; while H. Moissan observed that the iron contained granules of graphite, and amorphous carbon. All this favours the view that the iron has been reduced by carbonaceous matters on its way up from below. On the other hand, the iron is not always found in basalts or peridotites penetrating carbonaceous strata. E. B. de Chancourtois may be right in assuming that the iron has come up from great depths to teach us that the earth's interior is rich in uncombined metals. The suggestion of C. Winkler, and E. Weinschenk that the iron and nickel have been brought up from below as carbonyls is not so probable, because these gases are so unstable at elevated temps.; and C. Winkler observed no evidence of occluded carbon monoxide. The Disco Island occurrences have also been discussed by G. Tschermak, T. Nicolau, A. Schwantke, R. Nauckhoff, W. Wahl, C. Benedicks, J. L. Smith, S. Meunier, A. G. Nathorst, and A. E. Törnebohm. C. Winkler gave an analysis of a weathered sample; and analyses reported by G. Forchhammer, J. Lorenzen, F. Wöhler, A. Daubrée, N. Wyssotzky, E. T. Allen, W. J. Taylor, W. H. Melville, E. Cohen, J. S. Steenstrup, J. W. Mallet, G. S. Jamieson, G. C. Hoffmann, R. A. A. Johnston, A. Damour, W. Skey, A. A. Inostzanzeff, A. E. Kupffer, W. Irmer, J. G. Neumann, and J. L. Smith show the presence of up to 95·15 per cent. Fe; up to 2·55 per cent. Ni; up to 0·93 per cent. Co·; up to 0·48 per cent. Cu; up to 3·72 per cent. S; up to 3·11 per cent. C; and up to 4·18 per cent. SiO_2. J. D. Dana reported:

Fe	Ni	Co	Ca	P	S	Cl
94·71	2·25	0·63	0·24	1·82	0·29	0·06 per cent.

Native iron may also be of secondary origin. There are several reports where the iron has been reduced from its combinations. Thus, J. B. Tyrrell[3] observed masses of iron 15 to 20 lbs. in weight which have been formed during the burning of beds of lignite in contact with ironstone. The subject was discussed by A. Schwantke, P. Jeremejeff, J. Hector, G. vom Rath, G. H. F. Ulrich, J. von Szabo, W. H. Melville, G. C. Hoffmann, A. de Lapparent, J. G. Bornemann, T. G. Bonney and E. Aston. E. T. Allen found iron in borings in sedimentary rocks in Missouri near beds of coal; A. E. Kupffer found iron under peat, and it had been formed by the reduction of bog iron ore. A. A. Inostzanzeff cited a case of naturally-reduced iron near Vladivostock; M. Sidorenko, one at Gruschewka, Russia; G. C. Hoffmann, one at St. Joseph Island, Lake Huron; and E. Priwosnik, one at Shotley Bridge, England. The subject was discussed by J. F. L. Hausmann, F. M. Stapff, G. A. Kenngott, O. Vogel, and A. Reuss. J. F. Bahr found iron mixed with limonite and organic matter in petrified wood. The iron was called **sideroferrite**, and was supposed to have been produced by the decomposition of some salt of iron by the organic matter of wood.

There are reports of some specimens of native iron which may be really meteoric, and of meteoric iron which may be terrestrial. E. Hussak[4] found particles of native iron in an auriferous gravel in Brazil; A. Daubrée and S. Meunier, in the gold washings at Berezovsk, Urals; and W. Skey, in the drift of the Gorge River, New Zealand. In addition to the cases mentioned above, native iron has been

reported to occur in basalts, trap rocks, dolerites, magnetites, etc., of Great Britain,[5] France,[6] Italy,[7] Sweden,[8] Spain,[9] Germany,[10] Russia,[11] Africa,[12] Japan,[13] Canada,[14] United States,[15] Mexico,[16] Greenland [17]—*vide supra*—Brazil,[18] Australia,[19] and New Zealand.[20] The structure of native iron was discussed by C. Benedicks,[21] A. Schwantke, H. Fleissner, W. Eitel, W. Irmer, F. Hornstein, and K. Oebbeke and M. Schwarz.

Iron occurs also as an extra-terrestrial element. The spectra of the sun, and some of the hottest stars were shown by J. von Fraunhofer,[22] G. Kirchoff, J. N. Lockyer, C. E. Moore and H. N. Russell, C. Young, H. N. Russell, H. von Klüber, A. Secchi, H. A. Vogel, G. Rayet, J. N. Lockyer and F. E. Baxandall, A. Cornu, J. Parry, P. W. Merrill, E. M. Lindsay, C. G. Abbot, H. A. Rowland, S. Albrecht, C. E. St. John, M. N. Saha, S. A. Mitchell, H. M. Vernon, H. Deslandres, R. Furnhjelm, H. Ludendorff, J. Wilsing, H. Ebert, F. J. M. Stratton, G. E. Hale, G. E. Hale and co-workers, C. Fabry and H. Buisson, C. H. Payne, C. H. Payne and C. P. Chase, T. Dunham, J. Stebbins, W. S. Adams, W. C. Rufus, C. D. Shane, J. Storey, W. H. Wright, G. F. Paddock, E. P. Waterman, A. de Gramont, J. Hartmann, and F. McClean to indicate the presence of this element is those remote regions. H. von Klüber discussed the occurrence of lines of iron in the spectrum of the solar protuberances; E. A. Fath, of spiral nebulæ; and F. S. Hogg, and H. von Klüber, of comets; F. E. Wright, and B. Lyot found no evidence of the effects of iron in polarized light of the moon; but S. Mohorovicic included iron amongst the lunar elements. Meteorites are usually highly ferruginous, and contain metallic iron—**meteoric iron.**

Iron occurs in the metallic state in most meteorites; it may form the entire mass; or it may occur as a spongy, cellular matrix with imbedded grains of silicates; or in grains or scales disseminated in a stony matrix. A. Daubrée [23] applied the term **siderites** or **holosiderites** to meteorites of iron. These meteorites consist of iron alone or of iron associated with occasional veins of troilite, graphite or diamond, schreibersite, daubreelite, or lawrencite. When the Widmanstätten structure is absent, A. Brezina called them **ataxites.** The meteorites with a more or less spongy mass or network of iron, with embedded grains of chrysolite or other silicates, were called **siderolites** or **syssiderolites.** A. Brezina applied the term *siderolithites* to those with the iron network, and he considered two varieties—*mesosiderite* and *grahamite*; and he applied the term *lithosiderites* to those consisting almost wholly of nickel-iron, which he subdivided into *siderophyrs* and *pallasites.* A. Daubrée called the stony meteorites **sporadosiderites,** where the iron is more or less disseminated through the stony mass, and according to the relative abundance of the disseminated iron the sporadosiderites were called **polysiderites, or oligosiderites, or cryptosiderites**; and if no iron was present, **asiderites.** G. Rose called the stony meteorites with rounded spherical grains of enstatite or chrysolite, **chondrules**—χόνδρος, a spherule—and when the structure is more or less radiating, **chondrites**; and when free or almost free from iron, they were called *achondrites.* N. S. Maskelyne used the term *siderite* for meteoric iron, *siderolite* for lithosiderite and siderolite, and *aërolites* for chondrites and achondrites—the term " siderite " is in regular use for native ferrous carbonate. The subject has been discussed by C. von Reichenbach, G. F. Zimmer, G. Tschermak, M. E. Wadsworth, and C. U. Shephard, as well as in numerous monographs, catalogues of museum collections, etc.

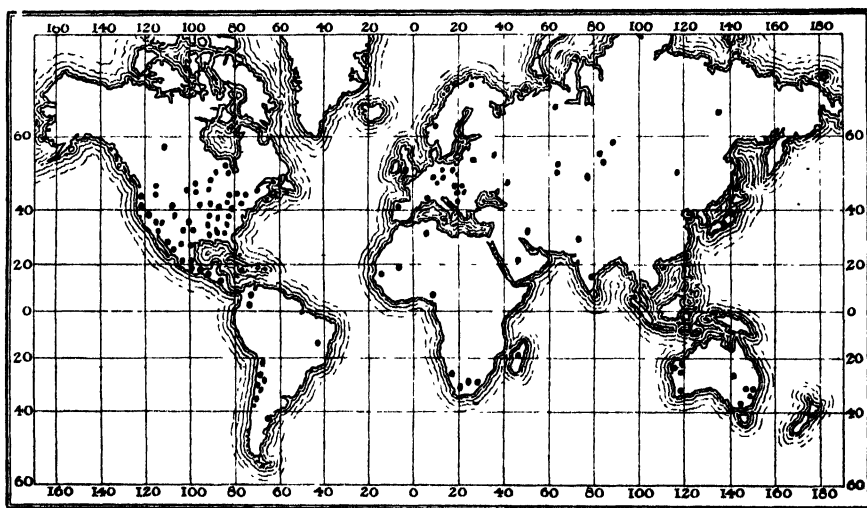
There are references in the *Bible* to falls of meteorites—*e.g.* Joshua (**10.** 11), *Psalms* (**18.** 13), *Acts* (**19.** 35)—and in several of the ancient Greek and Latin writers


FIG. 4.—Localities of Known Falls of Meteorites.

—*e.g.* Pliny, *Historia naturalis* (**2.** 58, and **37.** 51, 52, 61). E. F. F. Chladni [24] compiled tables in 1803 and 1815 ; and in 1860, P. A. Kesselmayer listed 647 falls between 1984 B.C. and A.D. 1860. Numerous other lists of known falls of meteorites have been prepared, and G. F. Zimmer's has represented the known localities in the map, Fig. 4. Recent lists of the known falls have been also compiled by E. Cohen, F. Berwerth, and H. Michel. F. Berwerth has calculated that the number falling on the earth at the present time is about 900 per annum. Allowing for the unknown falls and for the meteorites lost in the oceans, the earth is being well peppered with them every day. P. Kropotkin estimated that 146,000,000 small meteorites reach the earth annually, but they are so small that it would take 100,000 years for their dust to raise the surface of the globe a single inch. N. S. Maskelyne observed that the lighter surface of the meteorites is blown away as dust as the meteorite passes through our atmosphere, and in some cases the meteorite itself deflagrates with a more or less violent explosion, to form not a single

meteorite but rather a shower of fragments and dust. A. von Lasaulx discussed the nature of meteoric dust.

The first chemical analysis of meteoric iron was made in 1802 by E. Howard [25]; and in the next year M. H. Klaproth found that nickel was present in the meteorite from Agram. In 1815, F. Stromeyer observed the presence of cobalt, and in 1833, copper. The copper was confirmed by J. L. Smith. A. Laugier found chromium; J. J. Berzelius, phosphorus; C. T. Jackson, chlorine; A. Liversidge, J. C. H. Mingaye, and J. E. Whitfield and G. P. Merrill, gold, and the platinum metals; and S. Tennant, graphite—M. Eroféeff and P. Latschinoff observed diamonds in the meteorite of Novo-Urei, Russia; W. Will and J. Pinnow, in that of Carcote, Chile; and G. A. Koenig and A. E. Foote, in that of the Canyon Diablo, Arizona—discussed by C. Friedel, F. E. Mallard and A. Daubrée, and H. Moissan. In all, the following elements have been detected in meteorites: Na, K, Rb, Cu, Ag, Au, Ca, Sr, Ba, Mg, Zn, Al, C, Si, Pb, P, As, V, S, Cr, Tl, Mn, Fe, Co, Ni, Ir, Pt, Pd, and Ru. J. Lunt, A. P. Forjaz, and W. Crookes established the presence of some of these elements spectroscopically. A. W. Wright, T. Graham, W. Flight, J. W. Mallet, and R. T. Chamberlin observed that 0·97 to 47·13 vols. of gas may be occluded in meteoric iron, and that the occluded gas has from 14·54 to 85·68 per cent. of hydrogen; 0·12 to 43·29 of carbon dioxide; 4·46 to 71·05, carbon monoxide; 1·54 to 17·66, nitrogen; and up to 4·55, methane. W. Ramsay and co-workers, F. Paneth and co-workers, and H. D. Campbell and J. L. Howe found argon and helium amongst the occluded gases. R. J. Strutt, and T. T. Quirke and L. Finkelstein observed that many samples of meteoric iron are radioactive; and F. Paneth, D. Urry and W. Koeck measured the helium and radium contents of a number of meteorites, and made estimates of their age.

The average of 318 analyses of meteoric iron was calculated by O. C. Farrington and the results are here shown with the average previously given for the Greenland terrestrial iron :

	Fe	Ni	Co	Cu	Cr	P	S	C	Cl	
Meteoric .	90·85	8·52	0·59	0·02	0·01	0·17	0·04	0·03	—	per cent.
Terrestrial	94·71	2·25	0·63	0·24	—	1·82	0·29	— -	0·06	per cent.

The results are said to agree as closely as individual analyses of meteoric iron. F. W. Clarke has emphasized the chemical and mineralogical analogy between meteorites and the earth itself. F. Berwerth and H. Michel have compiled the results of 415 analyses of meteoric iron made [26] during the past century. According to O. C. Farrington, "the most striking feature brought out by the analyses is the relation between chemical composition and structure." This seems to be definite and general. All the meteorites of hexahedral structure have a nearly uniform composition, whilst amongst the octahedral meteorites fineness of structure increases with increase of nickel. Practically, the members of all the classes conform in composition to the average. G. P. Merrill found the average percentage of metallic iron in stony meteorites to be 11·98, and of ferrous oxide, 14·58, and 1·15 per cent. of metallic nickel; and O. C. Farrington gave for all meteorites :

Fe	O	Ni	Si	Mg	S	Ca	Co
72·6	10·10	6·50	5·20	3·80	0·49	0·46	0·44

Al	Na	P	Cr	K	C	Mn	Etc.
0·32	0·17	0·14	0·09	0·04	0·04	0·03	0·05

I. and W. Noddack's results are indicated in Table I, which shows F. W. Clarke and H. S. Washington's estimates of percentage proportions of the elements in the earth's crust, and F. Behrend and G. Berg's estimates of the percentage proportions of the elements in stony meteorites, in meteoric iron, and in troilite, as well as the relative abundance of the atoms when the value for oxygen is unity.

TABLE I.—THE DISTRIBUTION OF THE ELEMENTS IN THE EARTH'S CRUST AND IN METEORITES.

Element.	Earth's crust.	Meteorites.			
		Stony.	Iron.	Troilite.	Atomic proportions.
H	$8·8 \times 10^{-3}$	—	—	—	—
He	$4·2 \times 10^{-9}$	—	—	—	—
Li	$5·0 \times 10^{-5}$	$5·0 \times 10^{-6}$	—	—	$2·7 \times 10^{-5}$
Be	$5·0 \times 10^{-6}$	$1·0 \times 10^{-5}$	+	—	$4·2 \times 10^{-5}$
B	$1·4 \times 10^{-5}$	0	+	—	—
C	$8·7 \times 10^{-4}$	$3·4 \times 10^{-4}$	$3·9 \times 10^{-4}$	—	$1·9 \times 10^{-2}$
N	$3·0 \times 10^{-4}$	0	$1·0 \times 10^{-5}$	—	$1·9 \times 10^{-5}$
O	$4·942 \times 10^{-1}$	$4·204 \times 10^{-1}$	—	—	$1·0$
F	$2·7 \times 10^{-4}$	+	—	—	—
Ne	$5·0 \times 10^{-9}$	—	—	—	—
Na	$2·64 \times 10^{-2}$	$7·18 \times 10^{-3}$	—	—	$1·2 \times 10^{-2}$
Mg	$1·94 \times 10^{-2}$	$1·590 \times 10^{-1}$	$3·2 \times 10^{-4}$	—	$2·5 \times 10^{-1}$

R. T. Chamberlin [27] compiled Table II from the observations of A. W. Wright, J. Dewar and G. Ansdell, R. T. Chamberlin, T. Graham, J. W. Mallet, and W. Flight on the gases occluded in meteorites. The nickel influences the structure. It may also account for the change from a hexahedral to an octahedral structure, since the irons with hexahedral structure have the lowest percentage of nickel. The percentage of nickel in iron meteorites as a whole, as shown by reliable analyses, lies between 5 and 26 per cent. Cobalt in iron meteorites rarely exceeds 1 per cent. No constant relation in amount appears to exist between it and nickel, although, perhaps, as a rule it is higher with higher nickel. Analyses of meteoric iron always show iron, nickel, cobalt, copper, and phosphorus, and in most cases sulphur, carbon, and silicon. F. Paneth, and F. Paneth and W. D. Urry found up to $36·15 \times 10^{-6}$ c.c. of helium in meteoric iron.

The structure of the nickel-iron meteorites is discussed in connection with the iron-nickel alloys. In connection with these alloys, the relationship of **kamacite**, with over 7 per cent. nickel, **taenite**, with over 27 per cent. nickel, and **plessite**, a mixture of kamacite and taenite, is described. The structure of meteorites after polishing and etching shows that there are roughly three types : (i) Those with an octahedral structure are called **octahedrites.** They have two sets of parallel lines at right angles to one another, which gives rise to the so-called Widmanstätten structure or lines. The lines are produced by the alloys kamacite, taenite, and plessite. (ii) Those with a cubic structure or cleavage are called **hexahedrites.** They have lines intersecting at 120°. (iii) Those with an interrupted or indistinct structure are called **ataxites.**

The *phosphorus* in meteoric iron, forming **schreibersite** and **rhabdite,** is discussed in connection with the phosphides ; the *sulphur,* forming **troilite,** in connection with the sulphides, FeS ; the *carbon,* forming graphite or **cliftonite,** and carbides —**cementite,** or **cohenite**—in connection with the carbides, and the structure of iron and steel ; the *chromium,* forming chromite, and **daubreelite,** $FeS.Cr_2S_3$, in connection with the iron sulphides ; the *chlorine,* as **lawrencite,** in connection with ferrous chloride ; and the *silicon,* forming **moissanite,** SiC, in connection with silicon—there are also many ferruginous *silicates* present, *e.g.* plagioclase, pyroxene, olivine, etc.

Many of the specimens analyzed also had their sp. gr. taken. O. C. Farrington said that the sp. gr. of meteoric iron is between 7·6 and 7·9. Since the sp. gr. of purified iron is 7·85, it will be increased by that of nickel (8·8) according to the proportion of the latter. It will be decreased by accessory minerals such as troilite, FeS, of sp. gr. 4·7 ; schreibersite, Fe_3P, of sp. gr. 6·5 ; graphite, of sp. gr. 2·2 ; and oxidized ingredients, as well as by increasing porosity. C. Benedicks [28] discussed the electrical conductivity ; P. N. Laschtschenko and W. J. Iwanis, and P. N. Tschirwinsky, the passivity ; and H. H. Nininger, the oxidation of meteorites. F. Paneth and co-workers measured the relative proportions of helium and radium in meteorites, and calculated that the ages of meteorites ranged from 100 to 2600 million years. The solidification data indicate that these meteorites originated in our solar system. There have been observations by N. F. Belaiew,[29] C. Benedicks, F. Berwerth, W. Fränkel and G. Tammann, W. Guertler, H. Moissan, F. Osmond and G. Cartaud, F. Rinne, and F. Rinne and H. E. Boeke on the synthesis of meteoric iron—*vide infra.*

The list of minerals containing combined iron as an essential constituent is extensive. Comparatively few of the following minerals are of commercial importance. The industrially-important minerals, so far as the extraction of iron is concerned, include : (i) The magnetite group of ferrosic oxides ; (ii) The hæmatite group of anhydrous ferric oxides ; (iii) The limonite group of hydrated ferric oxides —*e.g.* limonite and brown iron ores ; (iv) The iron carbonate group—*e.g.* siderite ; (v) The iron silicate group—*e.g.* thuringite, chamosite, and glauconite ; and (vi) The iron sulphide group—*e.g.* pyrite and pyrrhotite. Some of these groups are of importance only under special conditions—*e.g.* in central Bohemia and Thuringia

chamosite and thuringite are worked commercially; and glauconite has been tried as a subsidiary to the recovery of its potash. The ferruginous minerals are exceedingly common, and a list would include the majority of known minerals. The following list includes those in which iron is usually considered to be always present:

Acmite, $Na_2Fe_2(SiO_3)_4$. **Actinolite**—a variety of grünerite. **Adelpholite**—weathered mossite. **Aegirite,** $Na_2Fe_2(SiO_3)_4$. **Ænigmatite,** $2(Na_2,Fe)O.2SiO_2$. **Almandine,** $3FeO.Al_2O_3.3SiO_2$. **Amaranite,** $Fe_2O_3.2SO_3.7H_2O$. **Amesite**—a ferruginous chlorite. **Ammoniojarosite,** $(NH_4)_2SO_4.3Fe_2O_3.3SO_3.6H_2O$. **Anapaite,** $FeCa_2(PO_4)_2.4H_2O$. **Andradite,** $3CaO.Fe_2O_3.3SiO_2$. **Andrewsite,** $4Fe_2O_3.2FeO.2CuO.3P_2O_5.7H_2O$. **Ankerite,** $2CaCO_3.MgCO_3.FeCO_3$. **Anophorite**—a variety of arfvedsonite. **Anthophyllite,** $(Mg,Fe)SiO_2$. **Aphrosiderite**—a variety of cronstedtite. **Arfvedsonite**—$Na_2O.FeO.4SiO_2$. **Argentojarosite,** $Ag_2SO_4.3Fe_2O_3.3SO_3.6H_2O$. **Argillaceous iron ore**—*vide* clay ironstone. **Arizonite,** $Fe_2O_3.3TiO_2$. **Arrojadite**—a complex ferrous manganous phosphate, $4R'_3PO_4.9R''_3(PO_4)_2$. **Arsenic,** $FeS_2.FeAs_2$. **Arsenical mundic,** $FeS_2.FeAs_2$. **Arsenical pyrites,** $FeS_2.FeAs_2$. **Arseniosiderite,** $6CaO.4Fe_2O_3.3As_2O_5.9H_2O$. **Arsenoferrite,** $FeAs_2$. **Astrolite,** $(Fe,Al)(Na,K)SiO_3.H_2O$. **Awaruite**—an alloy of iron and nickel—*q.v.* **Babingtonite**—a variety of hypersthene. **Baldaufite,** $Fe_3(PO_4)_2.3H_2O$. **Barkevicite**—a ferruginous amphibole. **Barnhardite,** $2Cu_2.S.Fe_2S_3$. **Barrandite**—hydrogel of ferric phosphate. **Bartholomite**—more or less dehydrated ferronatrite. **Beraunite,** $FePO_4.2Fe_2(PO_4)(OH)_3.4H_2O$. **Berlauite**—a leptochlorite. **Berthierite,** $FeS.Sb_2S_3$. **Beudantite,** $2PbO.3Fe_2O_3.As_2O_5.2SO_3.6H_2O$. **Bianchite,** $FeZn_2(SO_4)_3.18H_2O$. **Bilinite,** $FeSO_4.Fe_2(SO_4)_3.24H_2O$. **Bixbyite,** $FeO.MnO_2$. **Blackband**—a carbonaceous ferrous carbonate. **Blakeite**—an early name for coquimbite. **Blue iron earth**—an earthy variety of vivianite. **Bog ore**—hydrated ferric oxide. **Borgströmite,** $Fe_2O_3.SO_3.3H_2O$. **Borickite,** $2CaO.5Fe_2O_3.2P_2O_5.16H_2O$. **Bornite**—a sulphide of iron and copper. **Bosphorite,** $3Fe_2O_3.2P_2O_5.17H_2O$—colloidal. **Boryckite,** $CaO.2Fe_2O_3.P_2O_5.7H_2O$. **Botryogen**—essentially ferric sulphate, or $2MgO.Fe_2O_3.4SO_3.15H_2O$. **Brandisite,** $12(Mg,Ca,Fe)O.6(Al,Fe)_2O_3.5SiO_2.H_2O$. **Bronzite**—a variety of hypersthene. **Brush ore**—a variety of limonite. **Cacoxenite,** $2Fe_2O_3.P_2O_5.12H_2O$. **Calcioferrite,** $7FeO.2P_2O_5.2H_2O$. **Canbyite**—a ferruginous clay. **Carminite,** $3PbO.5Fe_2O_3.6As_2O_5$. **Carphosiderite,** $3Fe_2O_3.4SO_3.9H_2O$. **Castanite,** $Fe_2O_3.2SO_3.8H_2O$. **Cataphorite**—a ferruginous amphibole. **Catarinite**—an alloy of nickel and iron Fe_2Ni. **Chalcodite**—a variety of stilpomelane. **Chalcopyrite**—*vide* copper pyrites. **Chalcopyrrhotin,** $Cu_2S.3Fe_2S_3.2FeS$. **Chalcosiderite,** $3Fe_2O_3.CuO.2P_2O_5.8H_2O$. **Chalmersite,** $CuFe_2S_3$. **Chalybite**—*vide* spathic ore. **Chalypite**—a compound of iron and carbon. **Chamosite**—an iron silicate. **Chenevixite,** $3CuO.Fe_2O_3.As_2O_5.3H_2O$. **Childrenite**—hydrated phosphate of iron and aluminium. **Chloritoid,** $(Fe,Mg)O.Al_2O_3.SiO_2.H_2O$. **Chloropal**—a ferruginous clay. **Chloropite**—a variety of delessite. **Christophite**—a ferruginous sphalerite, $(Fe,Zn)S$. **Chrome iron ore**—*vide* chromite. **Chromite,** $FeO.Cr_2O_3$. **Chromitite,** $Fe_3O.Cr_2O_3$. **Chromoferrite**—*vide* chromite. **Clementite**—a ferruginous heptochlorite. **Clay ironstone**—an impure ferrous carbonate. **Cleveland ironstone**—a variety of clay ironstone. **Clinochlor**—a ferruginous chlorite. **Clinophæite**—an impure voltaite. **Clintonite,** $10(Mg,Cu)O.5(Al,Fe)_2O_3.4SiO_2.3H_2O$. **Cobalt-nickel pyrites,** $(Fe,Co,Ni)S_2$. **Cockscomb pyrites**—a variety of marcasite. **Codazzite,** $(Ca,Mg,Fe,Ce)CO_3$. **Cohenite,** $(Fe,Co,Ni)_3C$. **Columbite** or **niobite.** **Copiapite,** $3Fe_2O_3.8SO_3.27H_2O$, or else $2Fe_2O_3.5SO_3.18H_2O$. **Copper pyrites,** $Cu_2S.FeS_2$. **Copperas,** $FeSO_4.7H_2O$. **Coquimbite**—a hexagonal form of $Fe_2(SO_4)_3.9H_2O$. **Corkite,** $2PbO.3Fe_2O_3.P_2O_5.2SO_3.6H_2O$. **Coronadite,** $(Mn,Pb,Fe,Zn,Cu)_3Mn_3O_7$. **Corundophilite**—a ferruginous orthochlorite. **Cossyrite**—a variety of ænigmatite. **Crichtonite,** $FeTiO_3$. **Crocidolite**—a variety of riebeckite. **Cronstedtite,** $4FeO.2Fe_2O_3.3SiO_2.4H_2O$. **Crossite**—a variety of riebeckite. **Cubanite,** $CuS.Fe_2S_3$. **Cube ore**—*vide* iron sinter. **Daphnite,** $27FeO.10Al_2O_3.18SiO_2.28H_2O$. **Daubréelite,** $FeS.Cr_2S_3$. **Delafossite,** $CuFeO_2$. **Delessite**—a ferruginous leptochlorite. **Derbylite,** $2FeSbO_3.5TeTiO_2$. **Destinezite,** $2Fe_2O_3.2SO_3.P_2O_5.12H_2O$. **Diadochite,** $2Fe_2O_3.P_2O_5.2SO_3.2H_2O$. **Dietrichite**—an impure ferric alum. **Dimagnetite,** Fe_3O_4. **Douglasite,** $FeCl_2.2KCl.2H_2O$. **Dufrenite,** $Fe_2(OH)_3PO_4$. **Durdenite,** $Fe_2O_3.3TeO_2.4H_2O$. **Ekmanite**—a variety of cronstedtite. **Ekonorite,** $3Fe_2O_3.2P_2O_5.8H_2O$. **Emmonsite**—hydrated ferric tellurite. **Enophite**—a weathered chlorite. **Eosphorite**—a variety of childrenite rich in manganese. **Epichlorite**—a variety of leptochlorite. **Epigenite,** $4Cu_2S.3FeS.As_2S_5$. **Epiphanite**—a variety of leptochlorite. **Erubescite**—*vide* bornite. **Erythrosiderite,** $2KCl.FeCl_3.H_2O$. **Esmeraldaite,** $Fe_2O_3.4H_2O$. **Eukampite**—a variety of leptochlorite. **Euralite**—a variety of cronstedtite. **Fayalite,** $2FeO.SiO_2$—*vide* iron olivine. **Ferberite,** $FeO.WO_3$. **Ferrallophane,** $(Fe,Al)_2O_3.SiO_2.5H_2O$. **Ferrisymplesite,** $3Fe_2O_3.2As_2O_5.13H_2O$. **Ferritungstite,** $Fe_2O_3.WO_3.6H_2O$. **Ferronatrite,** $Na_3Fe(SO_4)_3.3H_2O$. **Ferropallidite,** $FeSO_4.H_2O$. **Ferrotellurite,** $FeO.TeO_3$. **Ferrovanite,** $2Fe_2O_3.2V_2O_5.5H_2O$. **Fibroferrite,** $Fe_2O_3.2SO_3.10H_2O$. **Flajolotite**—hydrogel ferric phosphate. **Fosterite,** $2(Mg,Fe)O.SiO_2$. **Foucherite**—like borychite and picite. **Franklinite**—*vide* zincite. **Gadolinite,** $FeO.2BeO.Y_2O_3.2SiO_2$. **Ganomatite**—colloidal ferric arsenate. **Gastaldite**—a variety of glaucophane. **Gelkielite,** $(Mg,Fe)O.TiO_2$. **Gillespite,** $FeO.BaO.4SiO_2$. **Gillingite**—a ferruginous clay. **Glaucodote,** $(Co,Fe)AsS$. **Glauconite**—an iron silicate. **Glaucophane,** $Na_2O.(Al,Fe)_2O_3.4SiO_2$.

Glockerite, $2FeO.Fe_2O_3.SO_3.6H_2O$. **Goethite**, $Fe_2O_3.H_2O$. **Graftonite**, $(Fe,Mn,Ca)_3(PO_4)_2$. **Gramenite**—a ferruginous clay. **Grengesite**—a variety of delessite. **Grünerite**, $FeO.SiO_2$. **Gudmundite**, $FeSbS$. **Halotrichite**, $FeSO_4.Al_2(SO_4)_3.24H_2O$. **Hæmatite**—crystals of ferric oxide. **Hæmatophanite**, $Pb(Cl,OH)_2.4PbO.2Fe_2O_3$. **Hastingsite**—a variety of riebeckite. **Hedenbergite**, $FeO.CaO.2SiO_2$. **Hercynite**, $FeO.Al_2O_3$. **Hetopazote**, or **heterosite**, $Fe_2O_3.P_2O_5.H_2O$. **Hisingerite**, $Fe_2O_3.2SiO_2.2H_2O$. **Hoeferite**, $2Fe_2O_3.3SiO_2.7H_2O$. **Hollandite**, $(Mn,Ba,K_2,H_2)MnO_5.n(Mn,Fe,Al)_4(MnO_5)_8$. **Holmquistite**—a variety of glaucophane. **Homilite**, $3CaO.FeO.B_2O_3.2SiO_2$. **Horse-flesh ore**—vide bornite. **Hudsonite**—a variety of glaucophane. **Hversalt**, an impure halotrichite. **Hydrogoethite**, $3Fe_2O_3.4H_2O$. **Hydrohæmatite**—vide turgite. **Hydrotroilite**, $FeS.nH_2O$. **Hystatite**, $FeTiO_3$. **Ihleite**, $Fe_2O_3.3SO_3.12H_2O$. **Ilmenite**, $FeO.TiO_2$. **Ilmenorutile**, $FeCb_2O_6.4TiO_2$. **Ilvaite**—see lievrite. **Iron glance**—vide specular ore. **Iron**, native. **Iron olivine**, Fe_2SiO_4. **Iron pyrites**—vide pyrites. **Iron sinter**, $2FeAsO_4.Fe(OH)_3.5H_2O$. **Iozite**, FeO. **Janosite**—a rhombic form of $Fe_2(SO_4)_3.9H_2O$. **Jarosite**, $K_2SO_4.3Fe_2O_3.4SO_3.6H_2O$. **Iron tourmaline**, $8FeO.6Al_2O_3.3B_2O_3.12SiO_2.4H_2O$. **Jollyite**—a ferruginous clay. **Josephinite**—an alloy of iron and nickel—q.v. **Kakoxen**, $2Fe_2O_3.P_2O_5.12H_2O$. **Kamasite**—an alloy of iron and nickel—q.v. **Kibdelophane**, $FeTiO_3$. **Kidney ore**, Fe_2O_3. **Knebelite**, $2(Fe,Mn)SiO_3$. **Koninckite**, $FePO_4.3H_2O$. **Kornelite**, $Fe_2O_3.3SO_3.7\frac{1}{2}H_2O$. **Kraurite**, $2Fe_2O_3.P_2O_5.3H_2O$. **Krausite**, $K_2SO_4.Fe_2(SO_4)_3.2H_2O$. **Kremersite**, $KCl.NH_4Cl.FeCl_3.H_2O$. **Kreuzbergite**—a ferric aluminium phosphate. **Lagonite**, $Fe_2O_3.3B_2O_3.3H_2O$. **Lake ore**—vide bog ore. **Laterite**—similar to limnite. **Lausenite**, $Fe_2(SO_4)_3.6H_2O$. **Lavenite**, $Na_2O.2(Mn,Ca,Fe)O.2(ZrO,F).4SiO_2$. **Lawrencite**—ferrous chloride. **Lazulite**, $(Mg,Fe)O.Fe_2O_3.P_2O_5.H_2O$. **Lehnerite**, $Fe_7(OH)_2(PO_4)_4.5H_2O$. **Lepidocrocite**—fibro-scaly goethite. **Leucopyrite**, $FeAs.FeAs_2$. **Lievrite**, $2CaO.4(Fe,Mn)O.Fe_2O_3.4SiO_2.H_2O$. **Lillite**—a variety of stilpomelane. **Limnite**, $Fe_2O_3.3H_2O$. **Limonite**, $2Fe_2O_3.3H_2O$. **Liskeardite**—hydrated arsenate of iron and aluminium. **Lodestone**—vide magnetite. **Löllingite**, $FeAs_2$. **Looking-glass ore**—vide specular ore. **Lossenite**, $2PbO.9Fe_2O_3.6As_2O_5.SO_3.33H_2O$. **Ludlamite**, $7FeO.2P_2O_5.9H_2O$. **Ludwigite**, $(Fe,Mg)O.Fe_2O_3.B_2O_3$. **Mackensite**, $Fe_2O_3.SiO_2.2H_2O$. **Maghemite**—native ferromagnetic ferric oxide. **Magnesioferrite**, $MgO.Fe_2O_3$. **Magnetic pyrites**, $4FeS.Fe_3S_4$. **Magnetite**, Fe_3O_4. **Magnetoferrite**, $2PbO.3Fe_2O_3$. **Metachroite**—resembles chamosite. **Magnetoplumbite**, $2(Pb,Mn)O.3Fe_2O_3$. **Magnoferrite**—vide magnesioferrite. **Manganhedenbergite**—a variety of hedenbergite. **Marcasite**, FeS_2. **Margarite**—a basic $Ca_2(Al,Fe)$-silicate. **Marmatite**, $FeS.4ZnS$. **Martite**, Fe_2O_3. **Masrite**—an impure ferric alum. **Mazapilite**, $3CaO.2Fe_2O_3.2As_2O_5.6H_2O$. **Melanolite**—a variety of leptochlorite. **Melanotekite**, $2PbO.Fe_2O_3.2SiO_2$. **Melanterine**—vide copperas. **Melnikowite**, $FeS_2.nH_2O$. **Menacanite**—vide ilmenite. **Mesitite**, $FeCO_3.2MgCO_3$. **Metavauxite**, $FeO.Al_2O_3.P_2O_5.4H_2O$. **Metavoltine**—a hydrated voltaite. **Micaceous iron ore**, Fe_2O_3. **Minette**—a hydrated Fe_2O_3. **Minguelite**—a variety of stilpomelane. **Mispickel**—vide arsenical pyrites. **Molysite**, $FeCl_3$. **Moravite**—a variety of cronstedtite. **Moronolite**—a variety of jarosite. **Mossite**, $(Fe,Mn)O.(Cb,Ta)_2O_5$. **Müllerite**—a ferruginous clay. **Mundic**—vide pyrites. **Narsarsukite**, $3Na_2O.(Fe,F)O.12SiO_2.2TiO_2$. **Natrojarosite**, $Na_2SO_4.3Fe_2O_3.3SO_3.6H_2O$. **Needle ironstone**—vide goethite. **Neptunite**, $(Na,K)_2O.(Fe,Mn)O.4SiO_2.TiO_2$. **Niobite**, $FeO.Cb_2O_5$. **Nontronite**, $Fe_2O_3.3SiO_2.5H_2O$. **Nordmarkite**—impure staurolite. **Ochre**—a variety of limonite. **Octibbehite**—an alloy of iron and nickel. **Olivine**, Fe_2SiO_4,Mg_2SiO_4. **Onegite**—vide goethite. **Orileyite**, $(Cu_2,Fe)_3(As,Sb)_2$. **Orthochlorite**, $2(Mg,Fe)O.Al_2O_3.SiO_2.2H_2O$ plus $3(Mg,Fe)O.2SiO_2.2H_2O$. **Osannite**—a variety of riebeckite. **Ottrelite**, $(Fe,Mn)O.Al_2O_3.2SiO_2.H_2O$. **Oxalite**, $2FeO.C_2O_3.3H_2O$. **Pacite**, $FeS_2.4FeAs_2$. **Paravauxite**, $5FeO.4Al_2O_3.5P_2O_5.26H_2O+21H_2O$; or $FeO.Al_2O_3.P_2O_5.5H_2O$. **Pattersonite**—a variety of leptochlorite. **Pelhamite**—a variety of chlorite. **Pennine**—a ferruginous orthochlorite. **Pentlandite**, $2FeS.NiS$. **Pharmaco-siderite**—vide iron sinter. **Phillipite**, $CuSO_4.Fe_2(SO_4)_3.nH_2O$—probably a mixture. **Phosphoferrite**, $7FeO.2P_2O_5.2H_2O$. **Phosphophyllite**, $3R_3(PO_4)_2.2Al(OH)SO_4.9H_2O$, where R represents Fe,Mg,Ca,K_2. **Phosphosiderite**, $2FePO_4.7H_2O$. **Picite**, $8FePO_4.6Fe(OH)_3.27H_2O$. **Pinguite**, $2Fe_2O_3.6SiO_2.Aq$. **Pisanite**, $(Fe,Cu)SO_4.7H_2O$. **Pistomesite**, $FeCO_3.MgCO_3$. **Pitticite**—an arsenical sinter. **Plagiocitrite**—an impure voltaite. **Planoferrite**, $Fe_2O_3.SO_3.15H_2O$. **Plinthite**—a ferruginous clay. **Plumboferrite**, $(Pb,Fe,Cu)O.Fe_2O_3$. **Plumbojarosite**, $PbSO_4.3Fe_2O_3.3SO_3.6H_2O$. **Prochlorite**—a ferruginous orthochlorite. **Pseudobrookite**, $Fe_2O_3.3TiO_2$. **Puddle ore**, Fe_2O_3. **Pyroxlerite**—a variety of leptochlorite. **Purpurite**—hydrogel ferric phosphate. **Pyroaurite**, $Fe(OH)_3.3Mg(OH)_2.3H_2O$. **Pyroxmangite**, $(Fe,Mn)SiO_3$. **Pyrrhotite**—vide magnetic pyrites. **Quenstedtite**, $Fe_2(SO_4)_3.10H_2O$. **Quetenite**, $MgO.Fe_2O_3.3SO_3.12H_2O$. **Red fossil ore**, Fe_2O_3. **Red hæmatite**—a generic name for anhydrous Fe_2O_3; and it is also given to turgite. **Red ochre**—vide turgite and red hæmatite. **Reinite**, $FeO.WO_3$. **Rhabdite**, $(Ni,Fe)_3P$. **Rhodonite**, $2(Mn,Fe)O.2SiO_2$. **Rhomboclase**, $\{Fe(OH)_2\}_2(HSO_4)_2.6H_2O$. **Rhodusite**—a variety of riebeckite. **Rhönite**—a variety of ænigmatite. **Richellite**, a ferric fluophosphate. **Richterite**—a variety of arfvedsonite. **Riebeckite**, $Na_2O.Fe_2O_3.4SiO_2$ mixed with $FeO.SiO_2$. **Rinneite**, $FeCl_2.3KCl.NaCl$. **Roemerite**, $FeSO_4.Fe_2(SO_4)_3.12H_2O$. **Röpperite**, $2(Fe,Mn,Zn,Mg)O.SiO_2$. **Rosenerite**, $(Fe,Mn,Ca)_2Al(OH)(PO_4)_2.2H_2O$. **Rubinglimmer**—vide goethite. **Rogersite**—an early name for lausenite. **Rubrite**, $MgSO_4.Fe_2(SO_4)_3.18H_2O$. **Ruddle**, Fe_2O_3. **Rumfite**—a variety of cronstedtite. **Salmonsite**—hydrogel ferric phosphate. **Salvadorite**, $(Cu,Fe)SO_4.7H_2O$. **Sammet-blende**—a velvety variety of goethite. **Sarcopside**, $2(Fe,Mg,Mn,Ca)_3(PO_4)_2.(Fe,Mg,Mn,Ca)F_2$. **Schafarzikite**,

FeO.P$_2$O$_3$. **Schrelbersite**, (Fe,Ni)$_3$P. **Schuchardtite**—a variety of chlorite. **Scorodite**, FeAsO.2H$_2$O. **Senaite**, (Fe,Mn,Pb)O.TiO$_2$. **Shining ore**—micaceous iron ore. **Sicklerite**, (Li,H)$_2$O.6MnO,Fe$_2$O$_3$.4P$_2$O$_5$.H$_2$O. **Siderazote**, Fe$_5$N. **Siderite**—vide spathic ore. **Siderochrome**—vide chromite. **Sideroferrite**—metallic iron present in petrified wood. **Sideronatrite**, 2Na$_2$O.Fe$_2$O$_3$.4SO$_3$.7H$_2$O. **Sider-plesite**, 2FeCO$_3$.MgCO$_3$. **Siderotile**, FeSO$_4$.5H$_2$O. **Sienna**, Fe$_2$O$_3$.Aq. **Sitaparite**, 9Mn$_2$O$_3$.4Fe$_2$O$_3$.MnO.3CaO. **Sjögrufvite**—hydrogel ferric phosphate. **Skemmatite**, 3MnO$_2$.2Fe$_2$O$_3$.6H$_2$O. **Slavikite**, (Na,K)$_2$SO$_4$.2Fe$_2$(OH)$_3$(SO$_4$)$_6$. 63H$_2$O. **Smith ore**—a variety of limonite. **Souesite**—an alloy of iron and nickel—q.v. **Spathic ore**, FeCO$_3$. **Soear pyrites**—a variety of marcasite. **Specular iron ore**, Fe$_2$O$_3$. **Sphæro-siderite**—a variety of clay ironstone. **Stainerite**, (Co,Fe,Al)$_2$O$_3$.H$_2$O. **Stannite**, Cu$_2$S.FeS.SnS$_2$. **Staurotite**, 4FeO.9Al$_2$O$_3$=8SiO$_2$.H$_2$O. **Steatargillite**—a variety of leptochlorite. **Strengite**, FePO$_4$.2H$_2$O. **Sternbergite**, Ag$_2$S.Fe$_2$S$_3$.2FeS. **Stilpnomelane**, 2(Fe,Mg)O.(Fe,Al)$_2$O$_3$.5SiO$_2$.3H$_2$O. **Striegovite**—a variety of cronstedtite. **Symplesite**, 3FeO.As$_2$O$_3$.8H$_2$O. **Szechenyite**—a variety of glaucophane. **Tænite**—an alloy of iron and nickel—q.v. **Talc-chlorite**—a variety of leptochlorite. **Tantalite**, FeO.Ta$_2$O$_5$. **Tapiolite**, FeO.Ta$_2$O$_5$. **Taramellite**, 4BaO.FeO.2Fe$_2$O$_3$.10SiO$_2$. **Taranakite**, like kehoeïte. **Tauriscite**, FeSO$_4$.7H$_2$O. **Thraulite**—a ferruginous clay. **Thuringite**—an iron silicate. **Titanic iron ore**, FeTiO$_2$. **Trevorite**, NiO.Fe$_2$O$_3$. **Triphyllite**, Li(Fe,Mn)PO$_4$. **Triplite**, 3(Fe,Mn)O.P$_2$O$_5$. (Fe,Mn)F$_2$. **Triploidite**, 4(Mn,Fe)O.P$_2$O$_5$.H$_2$O. **Tripuhite**, 2FeO.Sb$_2$O$_5$. **Troilite**, FeS. **Turgite**, 2Fe$_2$O$_3$.H$_2$O. **Uddevallite**, FeTiO$_2$. **Umber**, Fe$_2$O$_3$.Aq. **Unghwarite**—a ferruginous clay. **Urusite**, is sideronatrite. **Vallerilte**, Cu$_2$Fe$_4$S$_7$. **Vauxite**, 4FeO.2Al$_2$O$_3$.3P$_2$O$_5$.24H$_2$O+3H$_2$O, or FeO.Al$_2$O$_3$.P$_2$O$_5$.6H$_2$O. **Venasquite**, FeO.Al$_2$O$_3$.3SiO$_2$.H$_2$O. **Viridite**, 4FeO.2SiO$_2$.3H$_2$O. **Vivianite**, Fe$_3$(PO$_4$)$_2$.8H$_2$O. **Voltaite**, 3FeSO$_4$.Fe$_2$(SO$_4$)$_3$.9H$_2$O. **Vonsenite**, 4(Mg,Fe)O. Fe$_2$O$_3$.3B$_2$O$_3$. **Vredenburgite**, 2Fe$_2$O$_3$.3Mn$_3$O$_4$. **Weinbergerite**, Na$_2$O.6FeO.Al$_2$O$_3$.8H$_2$O. **Wenzelite**, (Fe,Mn,Mg)$_3$(PO$_4$)$_2$. **White iron pyrites**—vide marcasite. **Willcoxite**—a variety of heptochlorite. **Wolframite**, (Fe,Mn)WO$_4$. **Wood iron ore**—a variety of limonite. **Xantholite**—an impure staurolite. **Xanthophyllite**, 14(Mg,Ca,Fe)O.8Al$_2$O$_3$.5SiO$_2$.4H$_2$O. **Xantho-siderite**, Fe$_2$O$_3$.2H$_2$O. **Xanthoxenite**—basic ferric phosphate. **Yukonite**, (Ca$_3$.Fe$_2$)As$_2$O$_8$.2FeO(OH)$_3$.5H$_2$O. **Zincite**, (Mn,Fe)O.Fe$_2$O$_3$. **Zwieselite**—a ferruginous triplite.

The more important supplies of iron ore are sedimentary deposits, including replacement and residual deposits. E. C. Eckel[30] estimated that 10·7 per cent. were formed by direct or indirect igneous action; 26·2 per cent., by superficial weathering and chemical action; and 63·1 per cent., by direct sedimentary deposition.

I.—The igneous deposits include those which are found as original constituents of a mass of igneous rocks, but E. C. Eckel added that none at present worked in the United States can with certainty be ascribed to this group. The titaniferous magnetites, however, are generally supposed to be of magmatic origin. The subject was discussed by G. Berg.

II.—The sedimentary deposits include those in which the iron derived from the decay or weathering of a pre-existing rock has been transformed by running water either in suspension or in solution, and afterwards deposited by simple sedimentation, by evaporation, by chemical action, or by organic agencies, discussed by J. M. van Bemmelen—vide limonite. The sedimentary ores of the Rhine area, Middlesbrough, Belgium, France, Alabama, and Nova Scotia are of this character. The sedimentary rocks formed by the transportation of matter suspended in running water appear as transported concentrates, usually magnetite, along stream beds and sea beaches—vide infra, limonite. Deposits in which the iron is carried largely or entirely in solution by surface waters and afterwards deposited as a precipitate from the solution, include (1) *spring deposits*, which have been formed from spring-waters at their point of issue; (2) *bog deposits*, appearing as brown ores, pyrite, or carbonate in swamps or lakes; (3) *basin deposits*, in which the iron ore has been deposited in a completely or partially enclosed sea-basin by evaporation, chemical action, or organic agencies. The basin deposits include (i) the carbonate ores; (ii) iron silicate ores like the glauconites reported as forming extensive areas over the present ocean bed, and which are illustrated by the green sand deposits of New Jersey and the silicate ores of Thuringia, discussed by E. R. Zalinsky, C. Schmidt, and A. Lacroix; and (iii) the iron oxide ores exemplified by the Clinton ores of the United States, the Wabana ores of Newfoundland, the minette ores of Lorraine and Luxembourg, and the Minas Geraes ores of Brazil.

III.—Replacement ores have been formed by the deposition of an iron mineral

in a pre-existing mass of rock.   The iron has been carried to the place of deposition in solution—hot or cold.   The ferruginous waters may have been ascending or descending, and it may form (i) *cavity or pore deposits* by filling spaces pre-existing in the mass of rock ; (ii) *normal replacement deposits*, in which a mass of pre-existing rock has been replaced by an iron mineral, *e.g.* when soln. of iron salts act on limestones—*vide infra*, iron carbonates ; (iii) *secondary concentration deposits*, in which a low-grade ore has been enriched by the subsequent deposition of iron ; and (iv) *contact replacement deposits*, in which a mass of pre-existing rock has been replaced by an iron mineral deposited from heated solutions set in action by local igneous intrusions.

    IV.—Alteration ores.—These ores include (1) *Gossan deposits*, formed by the surface alteration of a pre-existing deposit of iron sulphide, discussed by H. M. Chance, E. Newton, J. W. Gruner, and T. S. Lovering ; and (2) *residual deposits*, formed during the decay or solution of a ferruginous rock, leaving the iron ore behind or newly formed *in situ, e.g.* lateritic ores—studied by H. Harrassowitz.

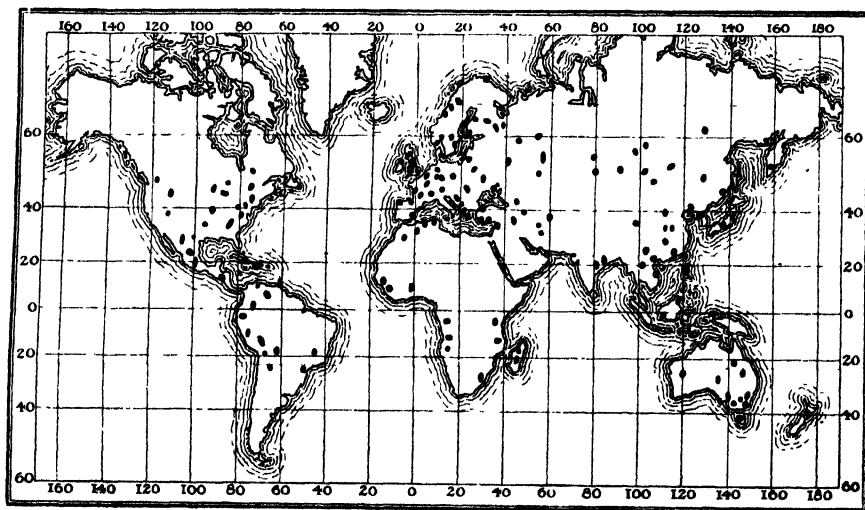
    An idea of the geographical distribution of the commercially important ores of iron can be gathered from the map, Fig. 5.   There are a number of works specially


FIG. 5.—Geographical Distribution of the Commercial Iron Ores.

devoted to this subject,[31] and the official geographical reports of many countries contain much data.

    Europe.—In **Great Britain** [32] there are the carbonate ores of the Mesozoic rocks of Yorkshire, Lincolnshire, and Northamptonshire.   They include the oolitic siderite of Cleveland, the deposit in Lincolnshire, which is continued in a less well-developed form in Leicestershire, the deposit of Rutland and Oxford, that in Northampton, and an analogous deposit in Inverness.   There are immense deposits of carbonate or clay iron-stone ores associated with the coal-measures, and which crop out in various parts, ranging from Newcastle-on-Tyne to South Wales ; they are mined extensively in Stafford-shire and Scotland.   The South Wales deposits were discussed by J. D. Kendall, H. Louis, S. Vivian, and M. Morgans.   The South Wales and Scottish deposits are outliers, and some of these ores—*e.g.* those of Northumberland—are carboniferous, but they do not belong to the coal-measures.   There are hæmatite and magnetite ores in Cumberland and Lancashire, where they are associated with the carboniferous limestone. There are lodes of red hæmatite of minor importance in Cornwall and Devon ; pockets of brown ore in Gloucester ; veins of spathic ore in Somerset ; pisolitic ores in Car-narvon (North Wales) ; and bedded oolitic ores in Wiltshire and Kent.   There are many other deposits which are of lesser ,importance or only of minor interest—

the Forest of Dean deposits, for instance, were discussed by J. W. Watson, and H. R. Insole and C. Z. Bunning. R. W. Dron described the iron ores of Shetland. The pisolitic, residual ores at Antrim in Ireland were discussed by H. Louis, C. H. Williams, W. Peile, A. McHenry, E. St. J. Lyburn, J. D. Kendall, E. Hull, C. S. Parnell, G. V. du Noyer, G. A. J. Cole, H. P. T. Rohleder, R. Tate and J. S. Holden, G. Kinahan, J. F. Hodges, and P. Argall. Clay ironstone occurs near Lough Allen and in Kilkenny county; while magnetite occurs at Ballycog. In France,[33] the region embracing the Lorraine-Luxemburg area is perhaps the most important iron district in Europe. The French portion of the deposits includes those of the Aumetz-Arsweiler Plateau, Fentsch, the Longwy basin—Hussigny, and Saulnes—the Briey basin—Orne, Landres, and Tucquegnieux—the Nancy basin, and the Crusnes basin—Grand-Rimont, Mercy-le-Hunt, and Audun-le-Roman. There are hæmatite and carbonate ores in western France, thus the Normandy deposits at May, Urville, St. Rémy, La Ferrière, Halouze and Larchamp, Dilette, etc.—the Anjou deposits—e.g. at Segré—the Brittany deposits—e.g. at Rougé and Nozay. There are also deposits in southern France—principally in the department of Pyrénées Orientales. In Luxemburg,[34] in Lorraine basin, there are the phosphatic minette ores—at Esch-sur-l'Alzette, Belvaux, Differdange, and Rodange. In Belgium,[35] there are a few low-grade deposits of hæmatite, but Belgium imports its main supplies from Spain, Sweden, and Germany. The principal iron mines are north of the Meuse valley—near Vedrin, Marchovelette, and Houssois. There is brown ore in the Campine district and also carbonate ore in the coal-measures of north-eastern Belgium. In Holland,[36] there are small deposits of bog ore in Groningen, Overyssel, and Gelderland. In Portugal,[37] there are small deposits not well developed. In Spain,[38] the most extensive deposits are near Moncorvo in Tras-os-Montes, Alemtejo in Odemira, and Porto de Moz in Estremadura. There are large deposits, some of which supply the demands of the British Bessemer steel process. There are hæmatite and carbonate ores associated with the cretaceous limestones of Bilbao, in the province of Vizcaya. There are brown hæmatites in the province of Lugo; and high-grade carbonates and hæmatites at Astorga and other parts of the province of Leon; while the provinces of Oviedo, Huelva, Sevilla, Almeria, Gerona, Murcia, Guipuzcoa, Navarra, Huesca, Pamplona, Logrono, Burgos, Segovia, Badajoz, Malaga, Granada, Santander, Saragossa, Teruel, and Guadalajara possess more or less important ores. When the ores of the Lorraine-Luxemburg region were ceded to France, at the conclusion of the 1914–18 war, Germany[39] lost about two-thirds of her estimated iron resources. The most extensive of the remaining deposits are in the Siegerland district of southern Westphalia and other parts of the east Rhine area—Dill-Lahn district, the regions of Taunus, Vogelsberg, Westerwald, Spessart, and Bergischer-Kalkberg. There are also iron ores in the Weser district, in the cretaceous rocks on the north of the Harz mountains, and the Salzgitter-Ilsede, the Harz mountains, Kellerwald-Sauerland, the Lower Hesse, Bentheim-Ochtrup-Ottenstein area, the Teutoburger Forest area; in the western Rhine area—near Aachen, and on the Soonwald; at Schmiedelberg in Silesia; at Amberg, Hollfeld, and Kressenberg in Bavaria; and in Würtemberg-Gieslingen, and Aalen. There are also deposits of bog iron in north and central Germany. In Poland,[40] there are low-grade spathic ores in the Czenstochau district of old Poland; brown ores in the Radom district—at Ilsha, Konsk, etc. There are also deposits in the districts of Warsaw, Kalisch, Wielun, Sieradz, Konin, etc. In Czechoslovakia,[41] there are extensive deposits in central Bohemia—Nucitz, Zditz, Krusnahora, Riesengebirge, and Erzgebirge; in the Szepes-Gömör area on the southern slopes of the Carpathian mountains in Ruthenia; on the east of March valley in the Sudetic mountains in Moravia; and there are old workings in the north-east Carpathians—in Zaros, Zemplen, Ung, and Bereg. In Bulgaria,[42] there are small deposits only of local importance at Blagoovest, Rudin-Kamak, Spassenije, and Kremikova. There are some deposits of iron ore in Albania.[43] In Jugoslavia,[44] there are deposits in Bosnia at Vares—Snireka, Drozkovats, Brezik, Slatina, Potoci, Borak, and Ponikva—and at Javorik near Ljubia—Stari Rieka, Adamusa, Drenovats, Stari Majdan, Sanski Most, Jazevats, Prevja, and Keska Ruda; in Serbia, brown iron ore is mined at Majdanpek, and there are deposits in the Kapaonik and the Zlalibor mountains—Mokra Gora, Mataruge, Massuritsa, Gevranitsa, Gare, Ruplje, Jabukovats, Lebeta, Korbeovats, Rupusite, and the Venchac mountains; in Serbian Macedonia there are deposits of brown ore at Babuna, hæmatite in the Osogov mountains, spathic ore at Dobrovo, and magnetite at Sredorek and Sracin; in Slovenia there are deposits near Assling, Jauerburg, Belshitsa, Lepene, Kropp, Kranz, Radovljitsa, Seisenberg, Weixelburg, Sittich, Ruppertshof, Nassenfuss, Jablanza, Thurmanhart, Treffen, Gonobits, Slemen, Seitz, Sallach, Schelesmo, and Preszka; in Dalmatia there are unimportant deposits near Bibenik, Kamenar, Ivine Vodice, and Kotlenitse; in Montenegro there are unworked deposits near Piperska and at Sozina; in Croatia there are deposits in the Velebit mountains, near Topusko, Gospits, Breslinats, Samobor, and Gjurmanets; and in Slavonia, at Poszega, Pleternitsa, Podvinij, Sibinj, and Sirats. In Rumania,[45] there is an iron industry centred in Banat—Resicza, Tvinova, Petrosz, and in the Bihar mountains; and there are deposits in Hunyad between Ruszkica and Also-Telek, between Gyalar and Also-Telek, and near Erdöhat, Aranyos, Batrina, and Kudzsir. There are deposits in Szeklerland, and in Suceava, Muscel, Gorji, Tulcea, Braila, and Mehedinti in old Rumania. In Switzerland,[46] there are deposits in

Fricktal, in Mount Chemin, at Chamoson, the Erzegg-Planplatten area, in the Delémont basin, and at Gonzen. Switzerland has hitherto depended for her iron on imports from Germany. In **Austria**,[47] there are important deposits of siderite and limonite at Erzberg in Styria, and at Donnersalpe, Glanzberg, and Polster in the Erzberg area; there are also deposits at Hüttenberg in Carinthia, and on the left bank of the Danube about 45 miles from Vienna. The iron ore deposits of **Hungary**,[48] before the adjustment after the 1914–18 war, were described by L. von Loczy and C. von Papp. In **Italy**,[49] the mines at Elba have furnished the greatest part of the output. The ore is high-grade, and low in phosphorus. There are deposits in Piedmont—Val d'Aosta, Traversella, Cogne, Liconi, Larcinaz, Colona, Carlo Muta, and Montchalet; in Sardinia—San Leone, and La Murra; in Lombardy—in the Brembana valley; in central Italy—La Tolfa, and the coastal regions of Tuscany from Monte Atsicco, in the Versilia district, and the north to Monte Argentario, and in the south to Orbetello district; in south Italy—at Stilo, etc.; and in Sicily—near Messina. In **Greece**,[50] there are important chromiferous or manganiferous iron ores in the Laurium peninsula, near Lake Kopais—at Lokris, Thebes, and Karditza in the province of Boitio; and at Tsouka, Lutzi, and Pavlorada in the province of Lokris—at Politka on the island of Euboea; at the Skyros mine west of the island of Skyros; near Spathi on the island of Zea; and on the islands Cerigo, Thermia, Seriphos, and Cyclades. In **Turkey**,[51] some iron ore occurs near Rodosto, and some magnetite near Samakov. Specimens of micaceous iron ore have been reported from **Cyprus**.[52] In **Russia**,[53] there are many important deposits of iron ore. There are important deposits in the Krivoi Rog basin in south Russia, and adjoining these are those of Lichmandeoskaja, the Sheltaja River district, at Korssak-Mogila in the Taurida district, and those in the peninsula of Kertch, in the Crimea. In central Russia there are deposits at Lipetsk in the Government of Tamboff; at Priklon, Slobina, Motmos, and Pessotschnaia in the Government of Vladimir; about Koschatinsky, and Duminitschsky in the Government of Kaluga; about Krapivno, and Bogorodizk in the Government of Tula; at Istijnsky and Syntulsky in the Government of Riasan; about Liwny, and Kromy in the Government of Orel. In the north Urals there are deposits about Bogoslovsky, near the Kolonja River, at Kutinskojoe, and at Voronzov. In the central Urals there are deposits near Kiselovsky, Troitsk, Cora Blagodat, Gora Wyssokaja, in the Alapaievsk district at Blagonadeshvoi, in the Neviansk district at Magorno Staroborowsko, Pitschuginsko, Reschewsko, Schwedsko, and Schuralinsko; in the Bilimbaievsky district at Ilmosko, and on the western slopes of the Bjelaja and Penkowaja mountains; and there are deposits at Versk-Isetsk. In the south Urals there are deposits in the Kussinskaia and Achtenskoje areas, in the Slatoust mining district, in the Komarowskaia area—at Karabijskoje, and Lemesinsky—in the group of hills of Magnitnaia Gora, in the Tscherdynsky district of the Government of Perm, and in the district of Glasowsky, and Slobodsky of the Government of Viatka. There are deposits in the Powenez area of the Government of Olonetz, and in the Jarensk area of the Government of Vologada. In **Finland**[54] there are iron ore deposits on the island of Jussarö, in the Porkonen-Pahtavaara area in Kittilä; at Juvakaisenmaa; and at Suojarvi. There are extensive deposits of bog ore in the lake country of central Finland; and titaniferous iron ore at Välimaki, on the north-eastern shore of Lake Lagoda. Iron has been produced in **Sweden**[55] for centuries; it was one of the most important centres in the later Middle Ages, since it had many accessible deposits of rich ore, an abundance of forests of coniferous wood as fuel, and ready access for transport. There are deposits of phosphatic ores situated mainly north of the Arctic Circle in the province of Norrbotten—including the Kiiruna and Gellivaara ore fields—at Kiirunavaara, Gellivaara, Malmberg, Luossavaara, Svappavaara, Leveäniemi, Mertainen, Ekströmsberg, Nakerivaara, Ylipäasnjarka, Tuolluvaara, Laukkujärvi, Altavaara, Painirova, etc., the Ruoutevare deposit, and one in the Vallatj mountains. In central and southern Sweden there are the important mining areas of Lomberg, East and West Ormberg, and also the deposits of Persberg, Norberg, Dannemora, Taberg, Herräng, Strippa, Strässa, etc. In **Norway**,[56] the main ores are not of the usual type. The country has low-grade ores which require concentrating for export. The ores for concentration occur at Sydvaranger, Fiskefjord, Blokken, Gullesfjord, and Oksfjord; there are also the Dunderland, Dunderford deposits—Urtvand, Vesteraali, Finkaataenget, Stensundtjern, Björhei, Urtfjeldmo, Strandfjord, and Nävernäs. There are also iron ore deposits near Ranenfjord, Fuglestrand, Seljelid, Elsfjord, Davemoen, Forsland, Sörovaagen, Risöen, Mosjöen, Dolstadaasen, Beieren, Naeverhaugen, Madstukrogan, Ofotenfjord, Haafjeld, Strand, Bervik, Kleven, Lenvik, Osmark, Narvik, Rombakfjord, Gratangen, Lavangen, Generalhaugen, Storhaugen, Loukostjokka, Sorreisen, Rollö, Andorgö, Dyrö, Tromsösund, Möllendalsakseln, Solliskaret, Kalvebaeklien, Solligangen, Langgangen, etc. Rich ores of magnetite and specular ore, ready for shipping without concentration, occur on the islands of Vesteraalen, Lofoten, Vestvaagö, and Gimsö, Oestvaago, Melövaer, Bjarkö, and Hindö. There are deposits near Beitstadfjord, Oelve, and Söftesdtad, west of Lake Nisservand, and between Arendal and Kragerö—Klodeberg, Braasted, and the Längo and Gomö islands. North of Kragerö are the so-called Fehn Mines, and towards the east there are deposits at Myrestö, Storemyr, Barmen, Narverud, etc. There are also deposits at Mistberg, and Skreia, north of Christiania. There are several small chrome iron ore deposits in Norway, and titani-

ferous ores at Koldal, Kyland, Storgangen, Blaafjeld, Laksedal, Rödsand, Surendalsfjord, Heindalen, Gusja, Rödsaeter, Meisingset, Lesjeskogen, Söholt, Solnördal, Oerien, Röddal, Sökelven, Vanelven, Sördalen, Sellenvold, Löland, Lavikdal, Lindaas, Rudö, Askeland, Lyseknappen, Lofoten, Vesteraalen, Langö, Oexnes, Flakstadö, etc.   There is also a deposit on **Spitzbergen.**[57]   There are iron deposits in the north-western peninsular of **Iceland.**[58]

Asia.—In **Palestine,**[59] a red and brown hæmatite occurs in the Ajlun district east of the River Jordan, between the Rivers Jabbok and Wadi Radjib.   In **Syria,**[60] some iron has been found at Anatolia in **Asia Minor.**[61]   In **Mesopotamia,**[62] iron ore occurs in the Sergusa Hills, north of Amadia; there are deposits east of Amadia, and in the Dohuk district, and in the valleys of the Bohtan and Tigris.   In **Arabia,**[63] deposits of red oxide are worked at Ras-el-Kheimah, and small deposits occur in the province of Yemen, and on the island of Dalmah.   In **Persia,**[64] there is a deposit of red oxide on the island of Ormuz, and workable deposits of hæmatite in the Bishneh and the Durdur districts.   In **Turkey-in-Asia,**[65] there are deposits of iron ore in Anatolia, Ayasmand, Aidin, Brusam, and Adana.   Rich mineral deposits occur in Armenia, and Kurdistan—e.g. Diarbekr, Van, Bitlis, and Trebizond.   In **Transcaucasia,**[66] there are numerous deposits but no coal, and transport is difficult.   There is ore in the province of Kutais, Georgia—at Khamuli, Artirn, Ubissi, Shrosha, Tchabakh, and Kédabek—Mont Bdak-Burum, the province of Terek, near Lenkoran, near Poti, and near Dashkesan.   There are several deposits of pyrites in Georgia.   In the **Aden,**[67] and the vicinity some iron ores occur in varying amounts in the basalts and quartz-trachytes. In **India,**[68] in Assam, there is clay ironstone in the Abor Hills, and in the Khasi Hills the natives manufactured iron many years ago.   There is iron ore near Jaipur, Manipur, and in the Mikir Hills; and in Bengal, at Biher, and Orissa.   Deposits of laterite occur in the Rajmahal and Mallarpur areas, and they were at one time the chief sources of the native iron industry about Birbhum.   There are iron ores in the Raniganj, Mayurbhanj, Gurumai-shini, Okampad, Badampahar, Pol Lahara, Singhbhum, Bonai, Keonjhar, Hazaribagh, Manbhum, and Palamau.   In Bombay there are ores in the districts of Almedabad, Kaira, Panch Mahals, Surat, Bijapur, Ratnagiri, Rewa Kantha, and Sind.   In Burma there are ores in the states of Mandalay, Shan, and Khesi Mansam.   In the Central India Agency there are deposits in the Bijawar series—e.g. Bundelkland—in Gwalior—e.g. Bagh, Par Hill, Mangor, and Santow—in Indore—e.g. Barwai, Chikitimodri, Karondia, Mendikhaira, Nandnia, and between Bain and Sendrani—and in the valley of the Ken River in Punna, and in the Son valley in Rewah.   The Central Provinces is the chief centre for iron-smelting in small, indigenous blast-furnaces.   There are iron ores in the Drug (including Raipur) district—e.g. Dondi-Lohara, in the western hills of Kairagarh, near Jurlakhar in Nandgron, at Chutrala, Kumi, and Basantapur in Thakurtola, and at Worarland.   There are ores in the Jubbulpore district—near Khumbi, Bjeragogarh, Agaria, Sihora, Mansakra, Ghogra, Imalia, Jauli, Kanhwara Hills, Lora Hill, and Saroli ; in the Chanda district—near Asola, Bissi, and the hills of Chamoursi, Dewalgaon, Lohara, Poser, Pipalgaon ; in the district of Narsinghpur at Omarpani ; and in the district of Nimar.   In Hyderabad iron ore occurs in the Bidar district, south of Kaliani ; and Konasamudram in the Nizamabad district is said to have been one of the localities where steel for the famous Damascus sword-blades was manufactured.   Iron ore also occurs in the Warangal district, and the Singarenni coalfield.   In Madras iron ores occur in the districts of Arcot, Bellary, Coimbatore, Godaveri, Kistna, Kurnool, Malabar, Nellore, Salem, Trichinopoly, and Vizagapatam.   Large quantities of ore also occur in the Mysore state in the Bababudan Hills of Kadur district, in the Channagiri, Channarayapatina, and Malvalli.   Hæmatite occurs in the districts of Bannu and Hazara of the North-West Frontier Province.   In the Punjab there are deposits between the Jumna and Ravi rivers ; in the Patiala state between Chhapri and Jannpur, and near Dhanota and Sohla.   In Rajputana there are deposits in the states of Alwar at Rajgarh, and Jaipur near Nimla. In the United Provinces there are ores in Kumaon, Dechauri, Khurpa Tal, and Naini Tal. In Goa there are deposits which are a continuation of those in the Ratnagiri district of Bombay.   In **Ceylon,**[69] the iron ores are widely distributed but in relatively small quanti-ties near Pulmoddai, Tirukkovil, Kiribatgala, Ampitiya, Hanguranketa, Nuwara Eliya, Badulla, and Bandarawela.   There are deposits in **Burma,**[70] at Twinnge, north-east of Thondaung.   In the **Malay States,**[71] there are extensive deposits at Pondok Tanjong, near Dungun in Trengganu, about Kuala Kuantan in Pahang, in Kuala Batu Pahat in Johore, and on Kedah Peak in Kedah.   In **Borneo,**[72] there are deposits of limonite on Tagoho Hill, British North Borneo.   Clay ironstone occurs in Labuan, etc.   There are ores in Tanah Laut, near Tambaga, the island of Seboekoe, or Sebuku, and Pulu Laut ; in Western Borneo there is clay ironstone in the state of Palo—on the islands of Bessi and, Karimata, near Batu Bessi, Kapuas, Kandarwangan, Padjilu, and between Siluas and, Sidin ; and in Eastern Borneo, at Kusan, and Kutei.   Iron was also formerly manufactured in Borneo, but the industry virtually succumbed to the competition with European iron about the middle of last century.   Iron ores are widely distributed in Sarawak—par-ticularly at Ridjang.   In Brunei iron ores occur in the basin of the River Barram ; in Sabah near Kudat, on the hills between Tunder Batu and Punguh, and near Pinunguh. In **Siam**[73] in ancient times there was much iron mining and smelting, but at present very little is done.   In **Celebes,**[74] there are deposits in the Lacona district ; and in **Sumatra,**[75]

there are large deposits in the Lampong district.   In **Timor,** iron ore occurs in Laleia, Portuguese Timor, and chrome iron ore in Dutch Timor.   There are occurrences on the **Lesser Sunda Islands,**[76] *e.g.* Flores.   There are deposits of magnetite and hæmatite on the **Philippine Islands** [77] in the eastern cordillera of Luzon—in the Bulacan province, at Santa Inez, Rizal province, on the margin of the Mambulao-Paracale district in Camarines, etc. There are lateritic ores in the Surigao province, Mindanao Island.   In **Hong Kong** [78] and territory there are the Ma-On-Shan deposit, and occurrences north-west of Tide Cove, between Kam-Tin and Tsin-Wan, and north-west and south of the Lan-Tau Island.   In **French Indo-China,**[79] there are deposits of iron ore at Cu-van, and Thai-Nguyen in Tonking; at Phnome-Dek in Cambodia; in the provinces of Vinh, Quang-tri, Quang-Ngai, Quang-Nam, and Ha-Tinh.   There are deposits of chrome ore at Van-Am, and Nui-Nua in Thanh-Hoa; and titaniferous iron ore at Pagoda Point.   There are reports of iron ore in **Thibet,**[80] particularly near Chiamdo.   In **China,**[81] iron ore ranks next in importance to coal, the most important mineral.   The largest iron mines are at Huangshihkang, and Wuchang in Tayeh, Hupel province, where a good quality hæmatite is treated.   In the province of Shansi the deposits are somewhat irregular in quality and are suited to native methods of working, but not to modern blast-furnace work on a large scale.   In the province of Manchuria ore is worked on a commercial scale at Penchihu or Penhsihu, and native methods have been employed at Tiehling; there are deposits near Lishan, Aushan, Haicheng, Fushun, Hsiuyen, Kirin, and Sansing.   In the province of Anhui there is a large mine at Taochung, and there are mines in the Tungling district. In the province of Shantung there are deposits at Paoshan, Chefoo, and Chungpuchwang. There are iron ore deposits in the provinces of Shensi, Chihli, Kiangsu, Honam, Szechuan, Yunnan, Kewichow, Hunan, Kiengsi, Chekiang, Fukien, Kwantung, Kwangsi, and Mongolia.   There are deposits of iron and coal in the north of **Manchuria.**[82]   There are numerous iron ore deposits in **Japan** [83]; there are magnetite ores in the districts or prefectures of Adzumadake (Aomori); Rogi, Kebaraichi, Kamaishi, and Hitokabe (Iwate); Kamichuka (Fukushima); Kamo, and Higashi-Kambara (Niigata); Nakakosaka (Toschigi); Kahiru (Fukui); Mikato (Hiogo); Dorogawa (Nava); and Yanagigaura (Oita).   There are micaceous iron ores at Sennin, and Omoye (Iwate); Okuzu (Akita); Aone (Miyagi); Narabara (Fukushima); Akadani, and Sodeyama (Niigata); and Ito (Shimane).   There are red iron ores at Yonai, Asahishi, Isogozawa, and Yanagawa (Iwate); Aki, Anani, Soanji, Konotani, and Oyashiki (Kochi).   The brown iron ores of Japan occur at Abuta, and Wakatasapu (Hokkaido); Kotaki, Naone, and Taro (Iwate); Yanahara (Okayama); Takata (Hiroshima); Ofuku (Yamaguchi); Hirao (Oita); Kawatana (Saga); Maski (Miyazaki); and Makisone and Makurasaki (Kagoshima).   Iron sand occurs in the provinces of Izumo and Iwami (Shimane); Hoki (Tottori); Aki and Bingo (Hiroshima); Bitchu, Bizen, and Mimasaka (Okayama); Rikuchu (Iwate); Ugo (Akita); Mutsu and Hokkaido (Aomori).   The principal pyrite mines are at Limori (Wakayama); Yanahara and Hisagi (Okayama); Takara (Yamanashi); Kucho (Yehime); and Kamaishi (Iwate).   In **Corea,**[84] there are mines in the provinces of Wheng-hai, Kokai, Phyong-an, Heian-nan, and Keiki.   Iron ores occur abundantly in **Siberia.**[85]   In western Siberia there are deposits in the Tomsk region.   There are regions at Gurevskoe, at Altai, at Abakanskoe in the Minuoinsk region, near Karkaralinsk, and near Tyumen in the Tobolsk province.   In eastern Siberia there are deposits near Bratski-Ostrog, in the valleys of the Yenisei River and its tributaries, in the valleys of the Upper Lena and Kirenga, near Misosvk, and on the Tsagan-Khuntei range.   Iron ore is found in the Nerchinsk district—*e.g.* at Baleginsk, or Balyazinsk.   Iron ore is abundant around Yakutsk.   There are deposits in the provinces of Amur, Maritime, and Anadyr.   There are deposits at Bielaya-Gora, and at Sergievsk, Sudzukhe, Olginsk, Kamehatka, and north of Russian Sakhlin.

Africa.—In **Morocco,**[86] there are ores supposed to be of minor importance near Oudjda, Djebel Hadrid, the valley of the Oum er Rebra, the Atlas region, Ida ou Mahmoud, the valley of the Segsaoua, Immingount, Djebel Figuermi, and Tagelt, all under French influence; and near Melilla, under Spanish influence.   In **Algeria,**[87] in the department of Oran, there are deposits near Sebabna, Rar-el-Maden, in the Beni-Saf region, at Kristel, and a few smaller places.   In the department of Algiers there are rich ores between Cape Ténès and Cherchel, at Djebel Hadid, Temoulga, Rouina, Zaccar, Miliana, in the Blida district, near Fondouk, and at Aïn Oudrer.   In the department of Constantine there are deposits between the Soumman and Agrioum valleys, in the neighbourhood of Filfila, in the Aïn Mokra region west of Bône, Ouenza, and Bou Kadra.   In **Tunisia,**[88] there are deposits in the Nefzas region, at Douaria, Raz-er-Radjel, Djerissa, Slata, in the Harraba and Bou Jaber mountains, at Djebel Onk, and near Kef.   In **Egypt,**[89] in south-west Sinai, there are ores near Wadi Malha, Wadi Halliq, Nasb, and Wadi Baba.   In south-east Sinai there are ores at Wadi Um Agraf.   There are ores in the north-east desert on the seaward slope of the northern Gallala range, in the Red Sea hills, in the hills about Wadi Abu Marwat, and in the Wadi Abu Jerida; in the south-east desert in Wadi Suegat, and near El Ranga.   In the western desert oasis there are ores near Baharia, and at Gebel Ghorabi (Raven Hill).   The Nubian sandstone is highly ferruginous.   There are some deposits of iron in **Syria.**[90]   In the **Sudan,**[91] there are deposits in the Tokar region, in the province of

Bahr-el-Ghazal, the Upper Nile, and Mongalla, near Wadi Halfa, Kerma, and Dongola. The natives of south and west Sudan have smelted iron by primitive methods for many years. Iron ore is widely distributed throughout **Abyssinia.**[92] The deposits in the province of Tigré, in the hills around Addis Abbaba (Addi-Abbas) and the Enarea region are worked by the natives. Deposits have been reported in the Harrar (Harar) district at Hamoressa, Gobeli-Amoressa, Giarso, and near Boubassa. In **Kenya,**[93] formerly the British East Africa Protectorate, iron ore has been reported near the eastern border of the northern frontier district, and near Buttelu. Iron ores—particularly limonite—are abundant in **Uganda,**[94] e.g. near Kigezi, and Tororo. In **Tanganyika,**[95] formerly German East Africa, there are deposits on the west of the Hundussi mountains near Morogoro, in the districts of Upangua, Ruanda, and other places between Victoria Nyanza and the north of Lake Tanganyika have been worked by the natives; so also with deposits south-west of Karissimbi, the Mutare mountains, and west Ruanda. There are laterite deposits west of the Muscha mountains, and at Karambo, west of the Muwissi mountains, in the Jassenunu Mountain Pass, on the Kumutana mountain, etc. Iron ore occurs on the Kinga or Living-stone mountains, on the Liganga hills, in the Mahenge district, and in the Mkatta steppe. There are rich deposits near Karema. In the **Nyasaland**[96] protectorate, the ores are chiefly hæmatite and magnetite. There are deposits on the Mangui hill, the Ponkonyoma valley, the Sumbu district, the Namitawa Hills, north of the Northern Rukuru River, east of Panyanole in the Namalundo district, and the Malingundi Hill. In Cabo Delgado, or **Portuguese Nyasaland,**[97] iron ore has been reported about the Lujenda and Rovuma rivers. In **Madagascar,**[98] iron ore occurs abundantly—e.g. in the Ambatolaona region, and deposits of titaniferous ore in the Betsiriry region, and north of Tamatave. In **Mozambique,**[99] or Portuguese East Africa, there are deposits of iron ore in the Tete district, in the Manica region with its centre at Massikessi, or Macequece. There are here evidences of extensive ancient workings—particularly in the Inyamukarakara valley. Deposits have also been found on the sides of the Lusite valley, and the district of Mafusi. In **Swaziland,**[100] there are siliceous iron ores in the neighbourhood of Rigg's Peak, and near the border with Transvaal. In **Rhodesia,**[101] deposits of magnetite occur in the north, and there are laterite deposits near Lek Bangweolo. In the south there are pisolitic limonite deposits on the surface, and ironstone in the Kalahari, Karoo, and Lomagundi regions. Banded ironstone, etc., occurs between Gwelo and Umvuna, near Que Que, Shangani, and Sabi valley, and chromiferous or titaniferous magnetite occurs near Selukwe, Umvukwe, Lalapanzi, and Belingwe. According to A. J. C. Molyneaux, the iron outcrops in Zambesia were worked extensively by the ancients. In the **Transvaal,**[102] there are beds of titaniferous iron ore near Onderstepoort, at Maguet Heights in the district of Lydenburg, and in the Magalakwin valley. Chrome iron ore occurs midway between Lydenburg and Pieters-burg, near Ohrigstad. Magnetite quartzites occur near Pretoria, Potchefstroom, Airlie, Isberg, Lulukop, and Ermelo. Hæmatites occur near Malelane, Middleburg, Pullenshoop, Boschmanskop, Lyttleton junction, the Waterberg district, Crocodile River district, Donkerpoort, North Rustenburg district, and between Rhenosterfontain and Kromdraai. In **Cape Province,**[103] iron ore occurs in the beds extending 270 miles from the Prieska division to Bechuanaland. In **Natal,**[104] there are siliceous iron ores in the north part of the Uryheid district, in Zululand, and at Isibudeni; and titaniferous magnetite in the Tugela valley. There are limonite, hæmatite, and magnetite ores north-east of Dundee, at Doornberg, near Mount Kelly, and at Sweetwaters. There are surface deposits of pisolitic iron ore on the plateau west of Alverstone, the eastern slope of Hathorn's Hill, the townlands of Pietermaritzburg. In **South-west Africa,**[105] there are deposits north-west of Kalkfeld, west of Kaokoveld, south of Great Namaqualand, in Bastardland, and east of Keetmanshoop. In **Angola,**[106] a Portuguese possession, iron has been found in the valley of the Lukalla, and in Bailundo. There is also iron ore in **Portuguese Guinea,**[107] some of which has been worked by the natives on the Corubal River; likewise in Madeira iron ore occurs near Ponta do Sol. Iron ores are widely distributed in the **Belgian Congo.**[108] There are deposits near Katanga, near the Lualaba River, in the Kasei region on the northern slopes of the Angolan plateau, and in the Welle region on the north-east plateau. There are also deposits in the Maniema and Lake Kivu region. In the **French Congo,**[109] or French Equatorial Africa, iron ore has been reported in the region south of the Niari, on the right bank of the Jue or Djoue River, between Brazzaville and the sea, as well as farther south near Boko Congo. In the **French Cameroon,**[110] formerly German Kamerun, iron ore occurs near the Sanaga River, and near Yabasei; also in Laka, and in the Mandara mountains. In **French West Africa,**[111] laterite occurs in French Guinea and in Ivory Coast; titaniferous magnetite, and hæmatite occur in Dahomey. In Togoland massive hæmatite occurs at Banyeli, in the Sokede-Bassari district. Lateritic iron ore is abundant in Upper Senegal and Niger. Hæmatite occurs in the Yatenga district, and on the banks of the Bakhoy in the Mandingo district. Iron ore is said to occur in the Tagant and Ijil districts in Mauritania, where traces of native workings have been found. In **Spanish Guinea,**[112] there are ores in the regions of the Muni and Utamboni rivers, and on the island of Fernando Po. In **Nigeria,**[113] there are important deposits on Mount Patti, and others in the northern part of Bassa province—e.g. Assadam; in the Mumuye country in the Muri province. There are deposits at Panguru, east of Bauchi, Okuruku, in the Kabba

province, and there are iron ores at Atika, Anamu, Bangedde, between Jakura and Wa, Okeli, Ogein, Akwi, and Ojerami.   In northern Nigeria there are deposits at Oyo in the province of Lagos, and near Iseyin and Odo Ogun, west of Oyo ; also on the hill-slopes between Bali and Bamenda.   In the **Gold Coast**,[114] the clay ironstone east of the River Volta has been smelted by the natives at Dagomba, Pampamba, Buem, Kotokori, Gurma, and Mossi.   There are also deposits about Akpafu, Togoland.   In the negro republic, **Liberia**, the iron ores are in some cases worked by natives.   Deposits occur near Monrovia, at Cape Mount, in the Finley mountains, and near Careysburg.   Nearly all the inland territory remains unexplored.   In **Sierra Leone**,[115] there are lateritic ores along the inner margin of the coastal plain—near Devil's Hole, Waterloo, between Freetown and Tombo, and over a large part of the Koinadugu plateau.   Titaniferous magnetite occurs on the western side of the Bathurst Mountain.   In **Gambia** iron has been found in the cliffs of Kossoun, and Sami Tenda, the Kossema plateau, and the hills of Medina and Eda.

In **Greenland**,[116] telluric iron ores have been reported at Disco.

North America.—In **Canada**,[117] there are numerous deposits of iron—magnetite, titaniferous magnetite, ilmenite, hæmatite, limonite, and siderite.   In *Nova Scotia*,[118] there are deposits in the Nictaux-Torbrook area, in the vicinity of Clementsport, Margaretsville, north of Middleton, between Chute and Young Coves south-west of Mount Hanley, and north of Annapolis.   There are also deposits in the Hants County in the Goshen and Rocky Brook areas ; in the Colchester County in the areas of Brookfield, Clifton, and Londonderry ; in the Pictoci County in the Sutherland-Meikelfield area and on the South McLellan Mountain : in the Antigonish County in the Arisaig district, near Brown's Mountain, at Lochabar, North Lochabar, Pinkie Town, Soldiers Grant copper mine, Ireland, Polson Lake, McNaughton Brook, Polson Brook, and Caledonia Mills.   In the Guysborough County hæmatite has been reported at Erinville, Atwater, Guysborough, Moon Point, and Bigsby Head.   Magnetite and hæmatite have been found in Kings County and Digby County.   In Cape Breton County there are deposits on the Coxheath Hills, between Sydney and East Bay, at Loran Harbour, Grand Mira, and the Barachois area.   In Inverness County there are deposits on the slopes of Skye Mountain, and at Iron Brook, at Campbell's Brook, at Logan Glen, and at Upper Glencoe.   In Richmond County a deposit of specular hæmatite and magnetite occurs at Robinson Cove. In *New Brunswick*,[119] the deposits of iron ore are rather poor.   There are occurrences in the counties of Gloucester, Carleton, Charlotte, Northumberland, Queens, St. John, and Sunbury.   In *Quebec*,[120] iron ore was mined and smelted under the French régime in the eighteenth century.   In the Argentenil County magnetite occurs near Grenville ; in Compton County, near Spalding ; in Gaspé County, on Gaspé peninsula ; in Megantic County, near Leeds ; in Ottawa County, near Hull, Ottawa City, and Templeton ; in Pontiac County, near Chats Falls ; in Beauce County, between the Plante and Gallway rivers, and near Beauceville ; in Lake St. John County, on the Alma Island, near Kenogami, and Bourget ; in Saguenay County, near the Bay of Seven Islands, the Natashquan and St. John rivers, and on the north shore of the St. Lawrence ; in St. Maurice County, near St. Boniface de Shawinigan ; in Terrebonne County, near Beresford ; in Charlevoix County, near St. Urbain, and Baie St. Paul ; in Wolfe County, Ham Township, Bersimis, Moisie, Mingan, and Natashqwan ;   and in Ungava, in Long Islands, Belcher Islands, Nastapokan Islands, Hopewell Islands, and along the Koksoak and Hamilton rivers.   In *Ontario*,[121] the production of iron ore exceeds that of any other Canadian province.   In the Rainy River district there are outcrops of magnetite and pyrrhotite along the Atikokan River between Kawene and Atikokan, on Hunter's Island near Knife, Cypress, This Man's and Jasper Lakes, near Watten, Halkirk, and the Seine Bay ; in the Kenora district, along the Winnipeg River between the Lake of the Woods and English River, west of Lake St. Joseph, near Lake Minnitaki, Dryden, and Bending and Keewatin Lakes.   In the Patricia district, near Lac Seul, Lake St. Joseph, and Sutton Mill Lakes.   In Thunder Bay district there are deposits on the Mattawin Iron Range, near Kashaboiwe, Loon Lake area, the Onaman Iron Range, and west of Windejokan Lake ; in the Algoma district there are deposits northwest of Michipicoten harbour, the Brant Lake property, the Alice property, Algoma, near Deroche, Bellevue, Aweres, Macdonald Meredith, and Aberdeen.   In the Sudbury district there are deposits near Nemegos, the Woman River area, Ridout, north-west of Lake Sahkatawichtah, Wakami, Groundhog River area, and Moose Mountain.   In the Timiskaming district there are deposits in the Mattagami River area, the Opasatika River area, near Munro, Warden, Leonard, Boston, Otto, Dack, and Letchford.   In the district of Nipissing there are three iron ranges at the north-eastern arm of Lake Timagami, near Matagama Point, Austin Bay, east of Emerald Lake, and Huron Mountain west of Lake Manitopeepagee.   In Haliburton district there are deposits near Lutterworth, Snowdon, Glamorgan, and Monmouth, in Peterborough County, near Anstruther, Belmont, near Crow Lake, and Chandos ; in Hastings County, near Carlow, Faraday, Dungannon, Mayo, Wollaston, Coehill, Tudor, Gilmour, Marmora, and Madoc ; in Renfrew County, near Grattan, Blithfield, Calabogie, and McNab ; in Frontenac County, near South Canonto, Palmerston, and Bedford ; in Lanark County, near Levant, Darling, White Lake, Dalhousie, South Sherbrooke, Christie's Lake, and Bathurst ; and Leeds County, near North Crosby, and South Crosby about Mud Lake.   No important deposits of iron ore have been

found in *Manitoba*,[122] but iron ore has been found north of the Riding Mountain, and in the Assiniboine valley, about Knee Lake, Rice Lake, and Star Lake, and Black Island on Winnipeg Lake. In *Saskatchewan*,[123] there is a deposit south-east of Black Bay, Lake Athabaska. In *Alberta*,[124] there are many deposits, but none has been found of sufficient size to warrant commercial development—*e.g.* along the Red Deer River, the Peace River, Athabaska valley, north of Lake Athabaska, north-east of Black Bay, at Tsu Lake, near Red Creek, Blairmore, and Sheep River near Calgary. In *British Columbia* [125] very little iron ore has been produced. In Vancouver and adjacent islands there are deposits up Nixon Creek near Cowichan Lake; near Port Renfrew, or Port San Juan; Malahat Mountains; the Shawnigan Lake slope; on Salt Spring Island, and south-west of Vancouver Island. In the Alberni Mining Division there are claims located near Anderson Lake, Uchicklesit Bay, Tzartos or Copper Island, near Clifton Point, Santa Maria Island, near Cape Beale, and Broughton Range; in the Clayoquot Mining Division, near Head Bay, Kennedy Lake, Hesquiat Harbour, and Maggie Lake; in the Quatsino Mining Division, near Coal Harbour; in the Nanaimo Mining Division, near Nimkish Lake, and north of the Quinsam River; on Texada Islands, extending from Raven Bay to Pocohontas, and to Sturt Bay; on Queen Charlotte Islands—Graham, Louise, and Moresby; in the Atlin Mining Division, on Rant Mountain; in the Skeena Mining Division, on Iron Mountain; in the Omineca Mining Division, near the head-waters of Summit Creek; in the Bella Coola Division, on the north of Rivers inlet; in the Clinton Mining Division, in the Taseko valley, the Schwartz valley, the Frank Gott valley, and the Iron Creek valley; in the Lillooet Mining Division, near Pemberton Meadows; in the Ashcroft Mining Division, east of Thompson River near Lytton, and at the head of Nelson Creek; in the Kamloops Mining Division, at Cherry Bluff; in the Nicola Mining Division, near Nicola; in the Nelson Mining Division, near Kitchener; and in the Fort Steel Mining Division, at Bull River, Lamb Creek, and Sand Creek. There are many varieties of iron ore in **Newfoundland** [126]; two of the largest iron mines in the world are situated on the north-western shore of Bell Island, in Conception Bay.

The **United States** [127] iron industry dates from the early years of the seventeenth century. E. C. Eckel divided the country into four groups for convenience in considering the production of iron ore.

I. *The Lake Superior Region* [128] includes the states of Minnesota, Michigan, Wisconsin, and Iowa. In the Vermilion district, north-east Minnesota, there are ores near Tower, Soudan, and Ely; in the Mesabi Range, also in Minnesota, west of Lake Superior, deposits occur near the towns of Biwabik, Eveleth, Virginia, Chisholm, Hibbing, Nashwauk, and Coleraine; in the Cuyuna district there is an area 65 miles long and from less than a mile to 9 miles in width extending south-west from the west of Dulmuth. The Gogebic Range is south of Lake Superior and extends in Michigan and Wisconsin. The most important part of the iron ore district is in Michigan, although two-thirds of the formation extends into Wisconsin. The Menominee Range includes Iron Mountain and Norway, and it lies wholly in Michigan. The Marquette Range extends from Marquette on Lake Superior to Lake Michigan, and it lies wholly in the state of Michigan. There is a deposit of iron ore near Wankon in Allamakee County, Iowa.

II. *The Southern Region* [129] includes the states of Alabama, Georgia, North and South Carolina, Virginia, West Virginia, Tennessee, Kentucky, Maryland, Arkansas, Louisiana, Missouri, and Texas. The main source of supply of iron ore of the Southern States is the red oolitic ores or the so-called Clinton hæmatite. The ores resemble the minette ore of the Lorraine-Luxemburg area in type, but they have a different geological age. The Birmingham district is situated in the valley region of Alabama, on the east side of the Coosa coalfield, and the Warrior coalfield on the north-west. The area covered is 75 miles in length and 10 miles in width. Birmingham City is near the centre of this area. E. C. Eckel estimates that there are about a thousand million tons of red iron ore in Alabama. In the Chattanooga-Attalla region the red ore has been worked in mines extending from Attalla and Gadsden (Alabama) northwards to Chattanooga. In the Tennessee-Virginia region the red ore extends north-east across Tennessee from Chattanooga to Cumberland Gap, where it enters Virginia. In the Appalachian valley district brown iron ores occur as scattered deposits. There is a productive belt beginning in Vermont and following the boundary of that state and of New York. The belt continues along the borders of New York State with Massachusetts and Connecticut, and after a barren interval reappears in eastern Pennsylvania, when there is another barren stretch and the ore reappears in south-west Virginia and runs across Tennessee and Georgia into Alabama. In the Tennessee River drainage area there is a region where brown iron ores occur in north-west Alabama, middle Tennessee, and western Kentucky. The area is drained by the Tennessee River and its main tributaries. In north-eastern Texas there are many deposits of brown iron ore in a triangular region approximating 10,000 sq. miles. It is bounded on the north by an irregular line from Sulphur Fork, Cass Co., extending west and south through Dangerfield, Morris Co., to a little south of Quitman, Wood Co.; on the west it extends southwards irregularly through the west side of Smith Co., the east side of Van Zandt Co., and Henderson Co., the centre of Anderson Co., west of Palestine, and south-westerly to the Brazos River near Hearne. The southern limit crosses the Trinity River near Crockett, the

Neches River near Augusta, and the Sabine River, north-east of Sabine Co. The crystalline rock area east of the Appalachian valley includes magnetites, specular hæmatites, and brown ores. It includes the magnetites of Cranberry, North Carolina; the magnetites and hæmatite of Pittsville and Rocky Mount, Virginia; the magnetites of Carter Co., Tennessee; and the brown gossan ores of Ducktown, Tennessee; deposits of magnetites in Llano Co. and Mason Co., Texas. There are titaniferous and non-titaniferous magnetites in the west of North Carolina. The deposits of iron ore in Louisiana consist mainly of limonite.

III. *The North-Eastern Region* [180] includes the states of New York, Vermont, New England, New Jersey, Pennsylvania, Indiana, and Ohio. There is the Adirondack region, which includes deposits of magnetite. It approximates 12,000 sq. miles, and is situated in the north-east of New York State. There is also a deposit of titaniferous magnetite in the north-east corner of Rhode Island. The New Jersey and New York highlands include a belt of magnetites extending in Putnam Co. and Orange Co., New York State, and north-eastern New Jersey. The north-eastern states region includes brown iron ores which occur in western New England, south-eastern New York, northern New Jersey, and south-western Pennsylvania. The south-eastern Pennsylvania region contains magnetites. It includes a belt passing through New Jersey and across south-eastern Pennsylvania. New York and Pennsylvania regions of the Clinton red ores extend from the central part of New York State to the Niagara River, and continue for some distance beyond into Ontario, Canada. The Western Adirondacks includes a series of deposits of red hæmatites extending along the western flank of the Adirondack region in St. Lawrence Co., and Jefferson Co., New York. The Ohio and Pennsylvania carbonate ores are associated with the carboniferous rocks of western Pennsylvania and Ohio.

IV. *The Western Region* [181] includes the eleven states lying to the west of the eastern boundaries of Montana, Wyoming, Colorado, and New Mexico—that is, these four states along with California, Nevada, Washington, Arizona, Utah, Idaho, and Oregon, in all about one-third of the total area of the United States—but it produces only about 2 per cent. of the total output of the country. Most of that is from the Hartville region, Wyoming; the deposits of iron ore are situated in Laramie Co., near Guernsey. There are large deposits of iron ore in Iron Co., southern Utah. There are two mining areas, Iron Springs in the north of the state and Pinto Iron in the south. Some iron ores have been mined in Colorado and New Mexico, but the productive areas are approaching exhaustion. The iron ore deposits in the remaining states—California, Nevada, Washington, Idaho, Oregon, and Montana—have not been exploited to any great extent. The known deposits are numerous but small. There are the iron sands on the Pacific Beach described by D. T. Day, and H. V. Winchell. The iron ore deposits in **Alaska** [132] have not received much attention. There are deposits near Nome, Seward Peninsula; on Hinchinbrook and Knight Islands, Prince William Sound; and near Haines, Sitka district.

Very large deposits of iron ore occur in **Cuba.**[133] On the south coast, in the district about Santiago City, high-grade ores have been regularly worked since 1884. The ores are magnetite and hæmatite and they are chiefly worked at Sevilla, Firmeza, Daiquirri, and Berraco. On the north coast there are deposits of brown iron ore. In the Oriente Province, formerly Santiago de Cuba Province, at the eastern end of the island, there are the Mayari and Moa ore fields, from the former of which is obtained the so-called *Mayari iron.* The following is reported to represent the composition of typical Mayari pig-iron :

C	Mn	P	S	Nl,Co	Cr	V	Tl	Cu	Si
4·67	0·90	0·047	0·011	1·30	2·66	0·05	0·18	0·035	0·80%

In the south of the Oriente Province there are deposits in the Daiquirri area and in the Firmeza district; while in the Camaguey Province there are ore deposits in the Cubitas area north of the Camaguey City. In **Hayti** and **San Domingo,**[134] beds of limonite have been reported; beds of limonite also occur in **Porto Rico,**[135] east of Mayaguez. Specimens of hæmatite and magnetite have been found in the Northern Range of **Trinidad,**[136] and there are deposits in the Maraccas valley; red oxide in the district of Oropuche West; and a brown ferruginous sandstone in La Brea. The iron in the rocks of **Bermudas** [137] was discussed by W. L. R. Emmet.

There are numerous deposits of iron ore in **Mexico** [138]; only a few of them have been closely examined or worked. There are the Cerro de Mercado, or the Iron Mountain, north of Durango; Las Truchas and Calvaric in the state of Michoacan; El Mamey in the state of Colima; Las Vegas, near Vera Cruz; near Monterey in the state of Nuevo Leon; Monclova in the state of Coahuila; and Tequesquite on the isthmus of Tehuantepec. In **Honduras,**[139] high-grade magnetic ore occurs at Agalteca, and deposits of iron ore occur in the district of Petoa, in the department of Santa Barbara. In **Nicaragua,**[140] there are large deposits of iron ore in the Pis-Pis district. In **Costa Rica,**[141] there is a large deposit of iron sand on the Atlantic side of the republic.

South America.—In **British Guiana,**[142] magnetic ironstone occurs in the district of Aruka Yarakita in the north-west; and ilmenitic black sands occur in many other places. In **Dutch Guiana,**[143] a laterite ore occurs in the Donderbary Mountains. In **Brazil,**[144] there are important iron ore deposits in **Minas Geraes.** The area contains massive hæmatite,

specular hæmatite, and laminated micaceous hæmatite, with some conglomerates, as well as stream and gravel ores which require concentration. There are deposits at Pico d'Itabira do Matto Dentro, Pico d'Itabira do Compo, Santa Barbara, the central part of the state of Goyaz, the San Francisco region of the state of Bahia, and the Corumba district of the state of Matto Grosso. Magnetite occurs in the coastal region of Sao Paulo, Parana, and Santa Catharina. In **Paraguay,**[145] iron ore is said to be abundant; there is limonite between the Apa and Aquidaban rivers; magnetite and hæmatite at Quiquio, Caapucu, and San Miguel. In **Uruguay,**[146] deposits of iron ore have been reported at Zapucay, San Juan, and at Piedra del Gigante in Minas. In **Argentina,**[147] a deposit of titaniferous magnetite occurs; but the known deposits are few and inferior. Magnetite occurs west of Albigasta in the Sierra de Ancasti, and east of Cerro Lacco in the province of Los Andes; and magnetite sands at Necochea and other parts of the Atlantic coast. In **Bolivia,**[148] iron ore has been reported in the province of Santa Ana. In **Chile,**[149] there are many deposits. The best known is the Tofo deposit in the province of Coquimbo, and in the same province there are deposits near Juan Soldado, Romeral, Pleito, Zapallo, Pejerreyes, Ovalle, and Illapel. In the Antofagasta province there are deposits near Potrero, north of Teltal; and in the province of Atacama there are deposits near Vallenar—*e.g.* Algarrobo, Ojes de Agua, and Chanar Quemada—and deposits near Chanaral, Copiapo, Tierra Amarilla, and the Cristales district. In **Peru,**[150] the development of the iron ore has been handicapped by the lack of suitable transport. There are deposits at Marcona, Huacravilca, Aija, and Callaycancha. In **Colombia,**[151] there are small, inaccessible deposits near Amaga, Medellin, Antiquia, Bogota, and Zipaquisa. In **Venezuela,**[152] there are deposits at Manoa, at the foot of the Imataca mountains, the Sierra de Imataca, and Piacoa, up the Orinoco.

Australasia.—In **Queensland,**[153] there is a large deposit at Mount Leviathan, or the Black Mountain, Mount Pisa, Mount Philip, Fountain Range, Mount Lucy, Iron Island, Olsen's Caves, Kabra, Mount Morgan, Iron Gully, Alma Creek, Pleasant Creek, Kroombit, Degalgil, Many Peaks, Glassford, Cania, Spring Creek, Gold Diggings, Cabbage Tree, Riverston, Rolleston, Pittsworth, Biggenden, Mount Perry, Eastern Creek, and Mount Isa. In **New South Wales,**[154] there are deposits of iron ore at Coombing Park near Carcoar, Cadia, Mittagong district, and Chalybeate Springs. There are magnetite deposits in the Gulgong district, the Cowra district, Broula Range, the Wallerawang district, the Goulburn district, and Congwarrah in Beresford county. There are clay band ores in the upper coal measures in the Wallerawang and Lithgow districts, Capertee and Carlo's Gap district, at Rix Creek, Ravensworth, Westbrook Creek, and Illawarra district. There are basaltic iron ores in the neighbourhood of Mittagong, Bowral, Wingello, Capertee, between Moss Vale and Sutton Forest, and in the New England district. There are miscellaneous deposits in Milbang, Argyle county, near Gobondery, Talbragar in Bligh county, Goulburn, Bherweree in St. Vincent county, Walli, Lyndhurst, Hampton, and Kenilworth, Marulan Molong district, Wyaldra in Phillip county, in the districts of Newbridge, Blayney, Orange, Rylstone, Cudgegong, and Piper's Flat, and Wallerawang. There are titaniferous deposits north-west of Port Stephens, and aluminous deposits at Wingello. In **Victoria,**[155] there are deposits of iron ore on the south-western slope of Mount Nowa, Mount Tara, Alberton West, Mirboo, Leongatha, San Remo, Grantville, Sandstone Island, Mount Major, and the Whitfield district. In **South Australia,**[156] there are deposits at Iron Knob and Iron Monarch, west-south-west from Port Augusta, near Williamstown, near Victoria Harbour, Mount Jagged, Koolka, near Quorn, south of Mingary, Oodla Wirra, and Moonta. In **West Australia,**[157] there are lenticular lodes of hæmatite with quartz gangue associated with crystalline schists and allied rocks on the Koolan and Cockatoo Islands, Yampi Sound, around Kimberley, Pilbara, Ashburton—Mount Edith, Murchison district, Weld Range, Wilgie Mia, Mounts Taylor, Hale, Matthews, Yarrameedee, and Gould, Gabanintha east of Nannine, Edjudina and south-west of Lake Raeside, Mount Mason, Mount Gibson, and Southern Cross. There are lodes of goethite forming the weathered portions of pyrites and pyrrhotite beds with magnetite and ferruginous silicates at Mount Caudan and Koolyanobbing. There are superficial deposits of brown iron ores with a gangue of gibbsite, clay, or quartz forming masses associated with ferruginous laterites at Clackline, Waterfall, and Comet Vale. There are also soft, porous deposits of bog ore of recent origin along the southern and western coastline of the state, and also on the eastern side of Herdsman Lake. In **Tasmania,**[158] in the Beaconsfield district, there are deposits on Brandy Creek, Sugar Loaf, Mount Vulcan, Scott's Hill, and Barnes' Hill. In Dial Range and along Penguin Creek there is non-magnetic red hæmatite, and also in the Iron Cliff lode. There is the Blythe River iron ore deposit of red hæmatite; the Rutherford iron lode of red hæmatite; the Long Plain iron ore; the Zeehan deposits; and Nelson River deposits. Iron ore is known to occur in **Papua,**[159] in the Mount Louis area; and also near the Kebenau River in **New Guinea**[160]—formerly Kaiser Wilhelmsland. H. Cayley-Webster mentioned a native iron-forge which he found in the Kei Islands. The bellows consisted of two bamboo cylinders 3 ft. high, with bunches of feathers on sticks to form the pistons. There are also good deposits of iron ore in the French island of **New Caledonia.**[161] There are a number of deposits of iron ore in **New Zealand,**[162] but only that at Parapara, near the north-west corner of the South Island is worked; and there are

beds of iron sand on or near the coast in many localities of the western coast of the North Island.   There are deposits of minor importance at Waitangi River, North Auckland, at Cape Kerr, and in the Greymouth area.   There are also small deposits at Kawakawa, and Mount Royal, Palmerston.   Chrome iron ore is reported on the Dun Mountain, near Croixelles, and near Milford Sound.

The world's production of pig-iron has risen enormously in the past quarter of a century.   It was, in metric tons :

1800	1820	1840	1860	1880	1890
480,000	880,000	2,750,000	7,430,000	18,490,000	27,580,000
1900	1906	1910	1917	1920	1925
40,330,000	58,650,000	65,300,000	69,637,224	79,325,884	75,692,728

The results for 1925 in more detail are :

Great Britain	6,261,700	Luxemburg	2,325,929
Austria	373,921	Sweden	455,253
Belgium	2,502,352	India	886,602
France	9,797,719	China	363,780
Czechoslovakia	1,148,000	Japan	684,923
Germany	9,929,413	Corea	100,323
Finland	—	Australia	439,419
Italy	527,612	New Zealand	1,289
Holland	107,400	South Africa	—
Poland	309,596	Canada	596,475
Rumania	63,258	United States	36,700,566
Norway	86,542	Mexico	48,593
Hungary	91,810	Brazil	70,000
Russia	1,295,108		
Jugoslavia	3,439	Total	75,692,728
Spain	521,658		

E. C. Eckel[163] gave the results indicated in Tables III and IV for the output in metric

TABLE III.—THE WORLD'S PRODUCTION OF PIG-IRON.
(In Millions of Tons)

Year.	United States.	Germany and Luxemburg.	Great Britain.	France.	Russia.	Austria and Hungary.	Belgium.	Canada.	Sweden.	Spain.	Italy.	Other countries.	Total.

out of the blast-furnaces of the world, and the output is increasing. The prices of a standard blast-furnace iron—Derbyshire No. 3 foundry cast iron—varied in Manchester during 1922–29 from £5 7s. 11d. to £3 8s. 0d. per ton.

Obviously this enormous output has made the curious wonder how long available supplies of ore will last. Estimates have been made of the world's reserve stocks of available iron in different countries—neglecting, of course, the unknown but assumed internal core. Pessimistic estimates like those of A. E. Törnebohm, in 1910, say that if the consumption increases hereafter as fast as it did between 1893 and 1906, the available ten billion tons of ore with which he credits the world will be exhausted in about 40 years. If so, there is a prospect of an immediate iron famine, at which Burns might well have said :

> And forward though I canna see
> I guess and fear.

There are also optimistic estimates, like that of E. C. Eckel, who considers that A. E. Törnebohm's estimates are twenty times too low ; and that of H. M. Howe, who considers that the supply is incalculable, because as the richer ores become exhausted, poorer ores will be available, until " a large bed of 4 per cent. ore, perhaps even 2·5 per cent. ore, will become a veritable bonanza." Rock with 2·5 per cent. of gold is an extraordinarily valuable ore, and rock with 2·5 per cent. of copper is treated to-day as copper ore. This subject has also been discussed by F. Beyschlag, H. E. Boker, H. H. Campbell, J. F. Kemp, P. Krusch, L. de Launay, W. Oechelhäuser, G. Mehrtens, D. Forbes, J. Deby, R. Akermann, and A. Lindmann. The pessimistic estimate of A. E. Törnebohm was perhaps responsible for the collection of data for different countries by different experts for the International Geological Congress held at Stockholm in 1910, and these reports were collected in the publication *The Iron Ore Resources of the World*, Stockholm, 1910. H. Sjögren summarized in Table VII the various estimates, expressed in millions of metric tons, of the reserves for different countries ; and M. Roesler's results are summarized in Table VIII.

TABLE VII.—SUMMARY OF THE WORLD'S IRON ORE RESERVES (H. Sjögren).
(In millions of metric tons.)

Continent.	Actual.		Potential.	
	Iron Ore.	Metal Iron.	Iron Ore.	Metal Iron.
Europe . . .	12,032	4,733	41,029	12,085
America . . .	9,855	5,154	81,822	40,731

Asia . . .	260	156	457	283
Africa . . .	125	75	Billions	Billions
Totals . .	22,408	10,192	123,377	53,136

Iron is a constituent of most natural waters, but it is present in very small proportions. The presence of iron can be readily detected in oceanic waters, and also in the salts obtained by the evaporation of these waters. Observations were made by J. Usiglio,[164] A. Goebel, J. Roth, W. Dittmar, R. Quinton, A. F. von Sass, S. Robinet and J. Lefort, E. von Bibra, E. H. Ducloux, G. Forchhammer, and F. J. Malaguti and co-workers. C. Schmidt gave 0·0012 grm. ferrous carbonate per litre for the Baltic Sea, and A. Goebel, 0·0067 grm. per litre ; C. Schmidt, 0·0016 grm. per litre for the White Sea ; J. Usiglio, 0·003 grm. per litre for the Mediterranean Sea ; C. Schmidt, 0·0029 to 0·0065 grm. per litre for the Indian Ocean ; C. Schmidt, 0·0039 grm. per litre for the Red Sea, and 0·0049 for the South Sea ; C. Schmidt, 0·0019 to 0·0022 grm. per litre for the Atlantic Ocean ;

T. E. Thorpe and E. H. Morton, 0·0050 grm. per litre for the Irish Sea. Deep-sea deposits—manganese nodules, phosphatic concretions, red and marine clays, glauconite, and other sediments—reported by J. Murray and A. F. Renard,[165] L. W. Collet, etc., show that considerable proportions of iron may be present. Thus, F. W. Clarke gave 8·66 per cent. of Fe_2O_3 and 0·84 per cent. of FeO in the red clay.

At the beginning of this era Pliny, in his *Historia naturalis* (**35**. 52), says that *alumen* turns black when treated with pomegranate juice or nut-galls. The reaction was also mentioned by Dioscorides, in his *De materia medica*, a contemporary of Pliny, and by Paracelsus,[166] who employed the reaction as a test for iron in mineral water. R. Boyle showed that a soln. of an iron salt is blackened by decoctions of nut-galls, pomegranate, logwood, and other astringent vegetable matters. F. Hoffmann, and T. Bergman also used the reaction as a test for iron

in mineral waters; and A. S. Marggraf detected iron in rain-water, snow-water, and different mineral waters by a soln. of potassium ferrocyanide.

The waters of most rivers contain some iron salt in solution. Thus, H. St. C. Deville [167] found it in the waters of the Rhine near Strassburg; R. Finkener, the Spree; H. St. C. Deville, the Loire and the Seine; J. F. Hodges, in Loch Neagh; E. J. Maumené, the Vesle; T. Graham and co-workers, the Thames; H. Wurtz, the Delaware; and C. Schmidt, the Dwina.

The so-called **chalybeate waters,** or *ferruginous waters*, or *steel-waters* contain not less than 0·06 grm. of iron salts per litre, and the iron is probably present as ferrous hydrocarbonate, $Fe(HCO_3)_2$, although it may be reported in analyses as ferric oxide. In illustration of chalybeate waters containing much carbon dioxide and but a small proportion of soluble salts, R. Kremann [168] reported the waters of Altwasser; those of Württemberg, reported by H. von Fehling; Brückenar, by J. Scherer; Chateldon, by J. P. Bouquet; Frewalde, by W. Lasch; Hofgeismar, Kurhessen, by H. A. L. Wiggers; Langenschwalbach, by R. Fresenius; Lieben-

stein, Thuringia, by E. Reichardt, J. von Liebig, and M. W. Thüring; the Ambros-quelle and Karolquelle, Marienbad, by W. F. Gintl; Niederlangenau, Glatz, by T. Poleck; Rabbia (*antica fonti*), by J. Zehentner; Radeberg, by W. Stein and C. Bley; Reinerz, by R. Woy; Royat, Puy-de-Dôme, by L. Moissenet, J. Lefort, J. L. Lassaigne, and A. Duboin; Saratoga, New York, by C. F. Chandler and F. A. Cairns, A. H. Chester, and L. R. Milford; Schandau, by H. W. F. Wacken-roder and E. Reichardt; Schwendi-Kaltbad, Canton Oberwalden, by P. A. Bolley and M. Schultz; Spaa, by E. Gérard and H. Chaurin; and Steben, by F. von Gorup-Besanez, and E. Reichardt.

There are also chalybeate waters containing a relatively large proportion of · carbon dioxide as well as of sodium carbonate and sulphate in soln. For instance, the waters of Bartfeld, examined by C. von Hauer [169]; Birresborn, by H. Vohl, and H. Fresenius; Fideris and Graubünden, by G. Nussberger; Flinsberg, Silesia, by T. Poleck; Kochl, Bayern, by M. Pettenkofer; Radein, by J. Holm; and Vals-les-Baines, by G. A. C. de C. de Castelnau, L. P. U. le Verrière, and O. Henry. Chalybeate waters may also contain, in addition, relatively large proportions of calcium carbonate and sulphate. For instance, the waters of Antogast, reported by R. Bunsen [170]; Bad Elster, Saxony, by A. Goldberg; Carlsbad, by J. Roth; Contrexeville, Dept. Vogesen, by O. Henry, L. Dieulafait, and L. Moissenet; Driburg, by R. Fresenius, and H. A. L. Wiggers; Freyersbach, Schwarzwald, by K. Birnbaum, and R. Bunsen; Fairhaven Springs, Missouri, by P. Schweitzer; Göppingen, Württemberg, by H. von Fehling and C. Hell; Griesbach, by G. Rupp, and R. Bunsen; Krynica, Galicia, by H. Dietrich; Langenau, by F. von Gorup-Besanez; Lippa, by M. Say; Mittagong, by J. C. H. Mingaye; O jo Caliente, New Mexico, by W. F. Hillebrand, and W. Lindgren; Petersthal, Baden, by J. Nessler; Pyrmont, by C. Neuberg, F. J. Hugi, and R. Fresenius; Recoara, by G. Bizio, and P. Spica; Rippolsdau, by R. Bunsen, and H. Will; Santa Moritz, by A. Husemann, A. von Planta and A. Kekulé, E. Bosshard, F. P. Treadwell, and W. Gambel; Schuls, Graubünden, by A. von Planta; Vichy, France, by J. Bouquet; and Wildungen, by R. Fresenius. Yet another class of chalybeate waters contains ferrous sulphate—for instance, the waters of Alexisbad, examined by T. Pusch, [171] and H. Bley; Mitterbad, Tyrol, by L. von Barth and R. Wegscheider, and J. C. Wittstein; Ronneby, Sweden, by N. O. Hamberg; and Roufrage, by J. C. Essener. The radioactivity of the waters of some German iron springs has been discussed by A. Simon and K. Kötschau.

Other chalybeate waters have been reported—*e.g.* at Kaiserqueele, Aachen, by V. Monheim [172]; Actos, Greece, by J. Landerer; Berlin, by O. A. Ziurek; Bohrloch, Zwickau, by C. M. Kersten; Bibra, by M. Papp; Cusset, by O. Henry, and J. P. Bouquet; Doberau, by F. Schultze; Dornawatra, by C. von John, and C. von Hauser and C. von John; Dorna-Kadreny, Bukowina, by P. Pribram and F. Langer, and P. Pribram; Dinan, Côtes-du-Nord, by F. J. Malaguti; Aix-les-Bains, by E. Bonjeau; Dürkheim, R. Bunsen and G. Kirchhoff, and H. Laspeyres; Karlsbrunn, Silesia, by E. Ludwig; Kreis Witebsk, by C. Schmidt; Pont-à-Mousson, by L. Grandeau; Missouri zinc region, by C. P. Williams; Mountain View Mine, Montana, by W. F. Hillebrand; Paramo de Ruiz, New Granada, by L. Lewy; Pressburg, Hungary, by P. Weselsky and A. Bauer; Rockbridge Co., Virginia, by M. B. Hardin; Rome, by F. Manganini; Rastenburg, by E. Ludwig; Savoy, by E. Wilm; Stolykin, by C. Schmidt; Sour Spring, Tuscarora, by T. S. Hunt; Stettin, by R. Fresenius; Trefriw, Wales, by T. Carnelley; Trentschein-Teplitz, by C. von Hauer; Weinheimer, by G. Müller; Wien-Raaber Eisenbahn, by P. Weselsky; Wiesau, by E. von Gorup-Besanez; Saitama (Japan), by S. Yoshimura; and Zeche Johann, near Steele, by W. von der Marck. Many of the chalybeate waters also contain arsenic. [173] For instance, those of Alumwell, Missouri, reported by P. Schweitzer; Burtscheider Quelle, by R. Wildenstein; Egypt, by F. Raspe; St. Etienne, by X. Landerer; Levico, by E. Ludwig and R. von Zeynek; Orsola, South Tyrol, by C. F. Eichleiter; Roncegno, by R. Nasini

and co-workers, and M. Gläser and W. Kalmann; Shoal Creek, Missouri, by W. F. Hillebrand; Srebrenica, Bosnia, by E. Ludwig; and Vöslau, by H. Siegmund and P. Juhacz, and M. Bamberger and A. Landsiedel. There are also ferruginous waters of volcanic origin. For instance, the waters of California geysers, Sonoma Co., reported by T. Price [174]; Cove Creek, Utah, by W. T. Lee; Paramo de Ruiz, Colombia, by J. B. J. D. Boussingault; Pozzuoli, Italy, by S. de Luca; Brook Sungi Pait, Java, by F. A. Flückiger; Popocatapetl, by J. Lefort; Hot Lake, White Island, N.Z., by C. du Ponteil, W. Skey, and J. S. Maclaurin; and the Lakes of Taal volcano, Philippine Islands, by J. Centeno, G. F. Becker, and R. F. Bacon.

There are numerous reports on the natural waters of different countries.[175] The behaviour of ferrous carbonate in carbonic acid soln. is analogous to that of calcium carbonate. Deposits are formed around chalybeate springs, and stalactites are formed as in the case of calcium carbonate soln., only the ferrous carbonate is not very stable, and it readily changes to limonite—*vide infra*, ferrous carbonate, and limonite. The *iron sinter* or deposit near a chalybeate spring in Death Gulch, Yellowstone National Park, contained, according to W. H. Weed [176]:

SiO_2	Fe_2O_3	Al_2O_3	SO_3	H_2O and Organic matter
1·37	63·03	0·08	8·35	26·94 per cent.

The work of water in helping to distribute iron on the surface of the globe has been discussed by A. Daubrée,[177] V. M. Goldschmidt, W. Lindgren, and H. S. Washington. F. W. Clarke estimated that the average iron content of the rivers of the world, calculated as $(Fe,Al)_2O_3$, is only 4·76 per cent. of the total mineral content; and, added E. S. Moore and J. E. Maynard, this would be precipitated almost immediately by the electrolytes in sea-water, if present in the river in the colloidal form. According to W. Lindgren, the **iron cycle** in nature is somewhat as follows. Igneous rocks average about 6 per cent. of ferrous and ferric oxides, and in the more basic rocks 12 to 16 per cent. may be present. These rocks form the raw material from which nature manufactures commercial iron ore. Iron oxides, particularly magnetite, sink in the magmas to form strongly ferriferous rocks, even massive magnetite, usually accompanied by the faithful companions titanium, phosphorus, and vanadium. These differentiation products are sometimes brought to the surface as masses in the rocks or as dikes. Magnetite is also, though rarely in quantities, brought up by underground waters, that is, in pegmatite dikes. Much more abundantly it is carried up as the vapour of a salt, probably in combination with halogens. Absorbed by limestones, it takes the form of magnetite, pyrrhotite, and pyrite in contact with metamorphic deposits. Carried up by underground waters, it is deposited as veins and replacement deposits as pyrite, pyrrhotite, and other sulphides or as arsenides. In all these forms it makes deposits of economic importance, the sulphides and the apatite-magnetite mixtures being utilized only lately as metallurgical methods improved. These " hypogene " deposits may be contrasted with those formed by processes whose home is in or near the surface.

Meteoric waters circulating in the crust dissolve the iron of the rocks and when overloaded deposit it below as sulphides or carbonates—a process rarely of great economic importance. Surface waters oxidize all rocks in the zone of weathering and, particularly in the basic rocks, they find a suitable raw material for their concentrating action. Magnetite is washed down to form " black sand." All rocks are decomposed, yielding soluble iron salts easily oxidized or hydrolyzed to the ultimate sub-aerial product, ferric hydroxides. A large part of the iron of the rocks remains thus *in situ*, or is carried a little way maybe to replace limestone. Colloidal processes are at work in the weathered rocks, and they concentrate the scattered limonite to deposits of some importance. A smaller part stays in soln., as bicarbonates or sulphate, and is carried to the sea, there to give rise to new iron deposits. The continuous stream of soluble iron salts which reaches the shores from ferriferous regions of rock decay is largely precipitated by complex reactions

in the sea-water, in part biochemical, to form silicates (glauconite, chamosite) or carbonate (siderite), or hæmatite, the precipitate usually assuming the oolitic texture. In the littoral muds rich in animal ooze there is often enough sulphur to cause an abundant precipitation of colloidal iron sulphides, which later crystallize as pyrite or marcasite. In muddy waters rich in vegetable substances siderite may be precipitated, which later appears in the coal seams as "black bands." Epochs of uplift subject the hardened sediments again to limonitic alteration and soln., and the products are again swept to the sea.

Besides these major cycles there are minor paths of circulation, usually of biochemical nature. The plants need organic iron compounds, which they absorb from the soil, and after their death the iron returns to the soil ; or land animals, man included, feed on plants, absorbing their iron. Meat-eating animals, including man, feed on the plant-eating species, and obtain their iron from them or from the blood of other carnivorous beings. Similar cycles are in operation in the sea, but for marine inhabitants iron is less of a necessity than for those of the land. Essentially the secondary iron deposits are products of the land or the shores. There seems to be very little iron in the sea-water, perhaps $0.00x$ per cent. in the dissolved salts. It seems to be very readily removed, as in the case of phosphorus.

According to H. Harrassowitz, humic acids carry away alumina and ferric oxide from regions that are continually damp, thereby concentrating the silica ; and if humic acids be absent, the alumina and ferric oxide are moderately concentrated in mixed gels of silica, alumina, and ferric oxide ; whilst in regions alternately wet and dry, poor in humic acids, alumina and ferric oxide are strongly concentrated. Desert lands, free from humic acids, are enriched in silica and ferric oxide, whilst in the alternately wet and dry steppes, rich in humic acids, the silica, alumina, and ferric oxide form gels and are not transported.

G. Tissandier [178] observed particles of meteoric iron in atmospheric dust, and they could be separated by means of a magnet. The composition of atmospheric dust was discussed by J. A. Udden, E. E. Free, and A. Ditte. A. Bergeat named ferric chloride amongst the sublimation products of fumaroles.

About 1702, L. Lemery [179] observed that iron is present in the ashes of many plants. He said :

On s'apercevra que dans ce moment beaucoup de particules du charbon se hérissent et seront attirées par le couteau, s'y attachant de même que la limaille de fer s'attache à l'aimant. Cette expérience moutre que le charbon de miel contient du fer.

E. F. Geoffroy supposed that the iron was synthesized from its primal elements during the calcination, but L. Lemery showed that the iron is only separated, not synthesized, during the process. In 1747, V. Menghini discovered the presence of iron in blood.

Iron is one of the important elements concerned with enzymes and the living organism ; it is one of the component elements of hæmaglobin, which contains 0.43 per cent. of iron. This subject was discussed by N. Scharoff,[180] A. B. Macallum, A. N. Richards, J. Barcroft, L. Maquenne and R. Cerighelli, etc. The body of man is said to contain one or two parts of iron per 10,000, and the blood, according to I. Novi, about 5 parts in 10,000. The iron content of the liver was discussed by A. Guillemonat, and A. Guillemonat and L. Lapicque. G. Bunge found the proportion varied from 1.0 to 35.5 mgrms. per 100 grms. of liver in dogs and cats. According to A. Dastre, the liver of invertebrates can take up iron preferentially, so that the liver of the cephalopods contains 25 times more iron than the rest of the body. E. Auscher and L. Lapicque found that the spleen contains insignificant quantities of iron, except in pathological states, where the red corpuscles of the blood deposit hydrated ferric oxide, $2Fe_2O_3.3H_2O$. A. Guillemonat and G. Delamare observed that the lymphatic glands of various animals contain traces up to 0.38 part per 1000—after inanition the proportion decreases, and after splenectomy it increases. G. Bunge found 0.72 per cent. Fe_2O_3 in ash

of a new-born dog, and 0·12 per cent. in the ash of dog's milk, and he argued that the fœtus receives a store of iron through the maternal placenta previous to birth. Similar results were obtained with young cats, rabbits, and guinea-pigs. H. M. Fox and H. Ramage found iron to be present in the tissues of all the polychætes examined, and the evidence indicates that iron is a universal constituent of protoplasm.

According to A. B. Macallum, iron firmly combined is a constant constituent of animal and vegetable chromatin, and of nucleoli. The chromophilous substance in ferment-forming cells contains iron, and the cytoplasm of protozoan organisms, which probably also secretes ferments, contains an iron compound. According to G. Bunge, the iron in the yellow colouring matter of eggs is due to a nuclein, which during incubation normally furnishes hæmaglobin. Iron does not enter the organism when introduced as inorganic salts of iron, because these salts are not assimilated. In the stomach they produce chlorides, which in the intestine form hydrated oxide or carbonate, and finally sulphide, in which form the iron appears in the fæces. It is not the same with some ferruginous organic compounds, a subject discussed by G. Bunge, H. F. Hendrix, and A. Jacquet. According to A. Guillemonat and L. Lapicque, a healthy man excretes from the intestines about 20 or 30 mgrms. of iron in 24 hrs., but normal urine contains only traces of iron— P. Figaroli found that about a milligram per diem is excreted by man; while A. Dastre, and L. Lapicque said that the bile gives off about 5 mgrms. per day.

Iron is not an essential component of the chlorophyll of vegetables, but, according to A. Meyer, plants cannot produce normal chlorophyll in the absence of iron ; and, according to S. Winogradsky, and J. L. Raulin, *Aspergillus niger* can develop 900 times faster in the presence of iron compounds. According to A. B. Macallum, a compound of iron is present in the chromophilous substance of the cytoplasm of the fungi. The non-nucleated bacteria, owing to their minuteness, have, with one exception, given little evidence of the presence of an organic iron compound ; but the chromophilous portion of the central substance of the cyanophyceæ contains iron ; and iron is also present in the peripheral granules formed of cyanophycin. Iron is precipitated from soil soln. in arable land, and it is taken up by the roots of plants, which sometimes cause a decolorization of the soil in their vicinity, as indicated by A. Daubrée—*vide infra*, limonite.

§ 3. The Extraction of Iron

While man has had to do little more than purify gold as it occurs in nature, it has been necessary for him, so to speak, to create iron. When one considers that the art of working this metal, which combines so many industrial processes, which triumphs over so many difficulties and obstacles, and which makes use so ingeniously of fire to conquer iron, goes back to the remotest antiquity, to beyond the flood, one is disposed to regard the first thought about this wonderful art as a sort of inspiration.—R. J. HaÜy.

In the most primitive form of extracting iron from its ores, a mixture of the ore and charcoal was heated. The impurities formed a scoria or slag, and the remainder of the ore was reduced to a tough, porous, pasty mass of iron. The iron was withdrawn in porous blocks, called blooms, and these were put into another furnace and strongly heated. The iron was taken out and hammered into a compact mass so as to drive out any scoriaceous matters. The earliest furnaces had a natural draught, and they were generally erected on high grounds, in order that the wind might assist combustion. This method is used even to-day in some parts of Africa. C. V. Bellamy,[1] for instance, thus described the process carried out in west Africa, in the hinterland of Lagos :

The ore used is a siliceous hæmatite occurring in shale. It is roasted, and then pulverized in a wooden mortar. The pounded ore is then washed by women. A hole is dug in the ground about 2 feet deep and filled with water. In this, a woman stands and washes the ore in a tray about 18 inches in diameter. It is then subjected to a further and more careful washing by a second woman, seated on the ground near by. The ore is then conveyed to the furnace in a smelting shed, of which there are eleven in the village. Each shed is about 25 feet long and 16 feet wide, with a doorway at each end. The walls are built of clay, and are from 4 to 6 feet high. They are not carried up to the roof, but a space is left all round for light and ventilation. From the ground to the ridge of the roof the height is 25 feet. The furnace is in the centre of the shed. It is built of clay, and occupies a circular space 7 feet in diameter. Its height is 3 feet 9 inches. Opposite one of the doorways a depression in the floor gives access to the furnace. The dome of the furnace is bound round by a rope of twisted vines. In the centre of the bottom of the furnace is an aperture 3 inches in diameter which communicates with a short tunnel below the floor of the shed, to which access is obtained by a pit inside the shed. The shed also contains a small kiln for firing the earthenware tuyères, and an ore-bin, both being made of clay. The process of smelting occupies 36 hours, draught being supplied by nine pairs of earthenware pipes. These are only rudely shaped by hand around a stick, and but partly baked. The average diameter of each pipe is 1·4 inch. Selected slag from each successive smelting is used as flux. It is run off by opening the orifice in the bottom of the furnace. For removing the bloom, the clay seals over the six apertures are broken up, the earthenware pipes removed and thrown aside, and the doorway of the furnace opened. The contents of live charcoal are raked out, and the 70-lb. bloom removed in a red-hot state by a loop of green creeper. Subsequently it is broken up, with the aid of a stone, into convenient sizes and sold to smiths. The metal produced in this way is a natural forged steel, which by reheating by the native smith is brought down to a tool steel with one per cent. of carbon.

The frescoes in Egyptian tombs show that prior to the 18th dynasty they produced a draught in their furnaces by blowpipes, and four to six men are shown so engaged in melting metal. Drawings of furnaces with the draught worked by bellows appear on the frescoes of the 18th dynasty. The iron-smelting furnaces of Populonia, and those reconstructed by T. May from the remains at Wilderspool, near Warrington, and dating from about A.D. 410, consisted essentially of a cavity with a wall and covering of clay, with holes at the base for admitting a draught and for withdrawing the metal. They were usually built on sloping ground, and the remains show that coal was used with the charcoal for smelting. There is no proof that bellows were employed ; nor is there any proof that cast iron was produced in one furnace and converted into malleable iron or steel in another. The plant consisted of a kiln for roasting the ores, a smelting furnace, and a smith's forge. Minute samples of metal collected in a fluid state on the furnace bottom, but the smelting furnace yielded blooms of spongy iron. The fusion of the iron in the furnace, owing to the formation of cast iron, must occasionally have occurred when the temperature was higher than what was usually obtained. This, for example,

explains Pliny's statement indicated above, *mirumque cum excoquatur vena modo liquari ferrum.* A. Ure thus described the Indian method of extracting iron and manufacturing steel :

> The manner in which iron ore is melted and converted into wootz or Indian steel by the natives of the present day is probably the very same as was practised at the time of the invasion of Alexander, and is a uniform process from the Himalaya Mountains to Cape Comerin. The furnace or bloomery in which the ore is smelted is from four to five feet high; it is somewhat pear-shaped, being about five feet wide at the base and one foot at the top ; it is built entirely of clay, so that a couple of men may finish its erection in a few hours and have it ready for use the next day. There is an opening in front about one foot or more in height which is built up with clay at the commencement and broken down at the end of each smelting operation. The bellows are usually made of a goat's skin which has been stripped from the animal without ripping open the part covering the belly. The apertures of the legs are tied up and a nozzle of bamboo is fastened into the opening formed by the neck. The orifice at the tail is enlarged and distended by two slips of bamboo; these are grasped in the hand and kept close together in making the stroke for the blast ; in the return stroke they are separated to admit the air. By working a bellows of this kind with each hand making alternate strokes, a tolerably uniform blast is produced ; the bamboo nozzles from the bellows are inserted into tubes of clay, which pass into the furnace. The furnace is filled with charcoal, and lighted coal being introduced before the nozzles, the mass in the interior is soon kindled. As soon as this is accomplished a small portion of the ore, previously moistened with water to prevent it from running through the charcoal, but without any flux whatever, is laid on the top of the coals and covered with charcoal to fill up the furnace. In this manner ore and fuel are supplied, and the bellows are urged for three or four hours, when the process is stopped, the temporary wall in front broken down, and the bloom removed with a pair of tongs from the bottom of the furnace.
>
> In converting the iron into steel the natives cut it into pieces to enable it to pack better into the crucible, which is formed of refractory clay mixed with a quantity of charred husks of rice. It is seldom charged with more than a pound of iron, which is put in with the proper weight of dried wood chopped small, and both are covered with one or two green leaves (the proportion being in general ten parts of iron to one of wood and leaves). The mouth of the crucible is then stopped with a handful of tempered clay, rammed in very closely to exclude the air. As soon as the clay-plugs of the crucible are dry, from twenty to twenty-four of them are built up in the form of an arch in a small blast-furnace ; they are kept covered with charcoal and subjected to heat urged by a blast for about two-and-a-half hours, when the process is considered to be complete. The crucibles are now taken out of the furnace and allowed to cool ; they are then broken and the steel is found in the form of a cake rounded by the bottom of the crucible. Rude as the whole appears to be, yet to gain that point must have been the result of considerable experience. The formation of the bellows—the composition of the crucibles—the charging of the furnaces and crucibles —all tell of observation and experience.

The method as practised by the native smiths of Uganda is depicted in Figs. 6 to 8 by G. H. Davis. A hole is dug in the ground and lined with clay (Fig. 6) ; on this is placed a bed of charcoal; then burnt grass, reeds, etc., for lighting the furnace. About the hole is built a stack with lumps from ant-hills as refractory. Inside this is a lining of iron ore ; and charcoal is placed in the interior. The furnace is fed with air from bellows. The furnace illustrated by Fig. 7 is operated by five sets of bellows worked by hand, as illustrated in the diagram. A plan of the smelting-furnace is shown in Fig. 8. The subject was also discussed by F. Dixey, and R. G. Cumming.

FIG. 6.—Bed of Primitive Uganda Iron Furnace.

According to T. Turner, S. A. Bilgrami, E. P. Martin and H. Louis, R. B. Foote, C. Lemaire, J. T. Last, L. Guillemain, W. S. Routledge, I. E. Lester, R. A. Hadfield, T. H. Holland, C. von Schwarz, H. L. Stokes, J. Danvers, F. H. Wynne, F. W. Reid, G. Braecke, H. D. McCaskey, F. Hupfield, A. Ledebur, R. A. Dart and N. del Grande, E. Fuchs and E. Saladin, an analogous process was used in India, etc. H. Louis

and E. P. Martin, and F. H. Wynne described various forms of bellows used in India. Some observations on the early extraction of iron were made by P. Berthier, F. L. von Cancrin, C. Combes, M. Gazeran, F. J. von Gerstner,
FIG. 7.—Iron-Smelting in Uganda.

A. Gurlt, J. F. L. Hausmann, A. Ledebur, F. A. von Marcher, L. B. Guyton de Morveau, T. E. Norburg, T. A. Rickard, G. H. Rivius, B. Valerius, and C. M. Weld.

The Catalan process of extracting iron was formerly practised in the province of Catalonia, north of Spain, and also about Ariège, south of France. The furnace was used in the seventeenth century in Navarre, and Guipuzcoa in Spain, and it consisted of a shallow, oval cavity or hearth forming a kind of inverted truncated cone. A tuyère projected downwards and inwards over the middle of one of the long sides of the oval. The blast was supplied by two bellows working alternately.

FIG. 8.—Plan of Uganda Smelting-Furnace.

Various modifications in size and shape were introduced from time to time, and about the end of the seventeenth century the *trompe* was introduced for supplying a continuous blast of air, in localities where a fall of water from a height of a few yards was available. The theory of the *trompe* was discussed by G. B. Venturi [2] in 1800, and observations on the subject were made by M. Thibaud and M. Tardy, J. F. d'Aubuisson, and G. Magnus. The Catalan forge, or *la forge Catalane*, consists essentially of a furnace, a blowing machine, and a heavy hammer. It was described by T. Richard, J. François, and J. Percy. A general idea of the furnace will be obtained from Fig. 9. The so-called *Corsican furnace* was employed in Corsica from a remote period, and a few were in use in 1828. It was little more than a blacksmith's forge—Fig. 10. It was described by M. Sagey,[3] J. M. Muthuon, L. Cordier, P. C. J. B. Tronson du Coudray, and J. H. Hassenfratz.

In former times a bloomery smelting-furnace was much used in Sweden, Norway, and Finland, and it came to be called the *osmund furnace*—so named from the Swedish term *åfsumd, åfsmundtz,* or *osmund* for the bloom produced in this kind of furnace. The furnace was an oblong, rectangular cavity to receive the lump of

reduced iron ; there was a large opening at the side through which the lump of iron, or bloom, was extracted, and which during the working of the furnace was temporarily built up with stones. The inner lining of the furnace was a refractory rock,
FIG. 9.—Catalan Furnace.
FIG. 10.—Corsican Furnace.

and the space between this and the timber casing on the outside was filled with earth. The calcined ore was smelted with charcoal, and the resulting bloom was forged as required. The furnace was described by E. Swedenborg,[4] A. Wahlberg, A. Wehrle, P. R. von Tunner, R. Gontermann, M. Meyer, J. Percy, L. J. Igelström, C. J. B. Karsten, etc. The blast was obtained by two bellows worked by a treadle.

A **bloom** is an ingot of iron or steel or a pile of puddled bars which, by passing through a set of rollers, has been reduced to a thick bar and left for further rolling when required for use ; it also refers to a mass of iron which has undergone the first hammering—R. Plott, and M. Ray. The term is also applied to the ball or mass of iron from the puddling furnace which is to be hammered or shingled into a bloom—A. Ure. A **bloomary** or **bloomery** is the first forge through which the metal passes after it has been melted from the ore, and in which it is made into blooms—M. Lister.

FIG. 11.—The Osmund Furnace.

According to *Notes and Queries* (8. 27, 1907), the term *bloma* was in use *ante* 1000 A.D., as indicated in T. Wright and R. P. Wülcker's *Anglo-Saxon and Old English Vocabularies* (London, 1. 141, 1884), *ante* 1000 ; and in J. Mirkus' *Liber Festivalis*, published at the beginning of the fifteenth century. In this book it is said that devils made " blomes of brennyng yerne " at St. Brendan.
V. Biringuccio represented the pre-Roman smelting-furnace by Fig. 12 ; and it is supposed to date from the time of Hesiod. It was fired with wood. The remains of one in Jura are described by R. Schaur. It was built anew after each smelting. The so-called *Stückofen* resembled two osmund furnaces, one inverted above the other—Fig. 13. They were at one time in operation in various parts of Europe—Carniola, Carinthia, Syria, Hungary, etc. The larger furnaces were 10 to 16 ft. in height, and the blast was operated by bellows worked by a water-wheel. The product was a lump of unfused malleable iron—up to about 6 cwts. in weight. This was cut into parts or *Stücke*, which was then hammered in the usual manner. This furnace is considered to be the forerunner of the modern blast-furnace. G. Jars, C. J. B. Karsten, J. Percy, G. Agricola, L. Beck, J. C. Quantz, O. Krasa, and others have described the operation of these furnaces. The conditions in the *Stückofen* were so favourable to the formation of that highly carburized, relatively fusible product

known as cast iron, that when it was obtained it had to be subjected to a process of decarburization before it could be worked under the hammer. Indeed, the carburized iron was virtually a new metal, which could be readily cast into any desired shape and size.

J. J. Becher [5] is sometimes regarded as the discoverer of cast iron, but it is very doubtful if any one can be credited with the discovery of this material. Stove-plates appear to have been one of the earliest forms of iron-castings ; and, according to A. Schrödter, they were made at Nassau in 1474 ; and, according to A. Kippen-berger, at Eifel in 1497. J. Schwank said cannon for artillery were made from cast iron in 1544 ; and J. Goostray and co-workers, between 1520 and 1854, when rifled cannon appeared. According to O. Johannsen, observations on the subject were made by K. Brunner in 1547. L. Bickel stated that the earliest recorded date for the working of cast iron in the Haina monastery, Hessen, is 1555, but the working of the iron foundries goes back much earlier. For instance, an inventory of guns belonging to the Prince of Hessen is dated 1544. M. A. Lower suggested that cast iron was probably made in Sussex about the middle of the fourteenth century. P. Buchanan said that R. Hogge made a cast-iron cannon at Bucksteed, Sussex, in 1543. Cast iron was imported into England about 1500,
FIG. 12.—Pre-Roman Iron-Smelting Furnace.　　FIG. 13.—Primitive *Stückofen*.
and a large iron gun weighing 10,500 lbs. was cast in London in 1516 ; and, according to H. A. Dillon, two large cast-iron cannon were brought to London from Ireland during the reign of Henry VII. W. Treptoff has reviewed the use of cast iron for making cannon in the Middle Ages.

The development of the cast iron industry has been discussed by H. Alker, L. Beck, L. Bickel, K. Bimler, P. G. H. Boswell, O. Brandt, E. Bremer, R. Buchanan, C. E. Dana, P. Desbief, J. F. Daubuisson, W. Erben, O. Erlinghagen, A. Faber, J. Fernie, F. A. Foster, J. P. Frey, C. A. Gerhard, J. Goostray and co-workers, A. Guettier, J. H. von Hefner-Alteneck, C. F. Himes, A. Hirsch, J. E. Hurst, R. Jenkins, O. Johannsen, H. Kalakuzky, E. C. Kreutzberg, J. Laissus, A. Ledebur, K. Lind, V. Lohse, K. Luthmer, T. Makemson, G. Malkowsky, P. Martell, C. F. P. von Martius, W. Mathesius, S. Miller, C. Pardun, H. Pudor, B. Rathgen, M. Rotacker, H. Schmitz, E. Schneegans, J. Schwank, R. Siedel, K. Sipp, S. G. Smith, W. A. Tiemann, A. Thiele, W. H. Uhland, O. Vogel, and L. van Werveke.

The size of the furnace for making iron was gradually increased to save fuel and to reduce the cost of manufacture ; at the same time it was noticed that the accidental production of cast iron became increasingly frequent, because the iron remained a longer time in contact with the fuel—charcoal—and it thus became more highly carburized. For a time the *Stückofen* was used for producing both the malleable iron blooms and molten cast iron. The furnaces which replaced the *Stückofen* were called *Bauerofen*, *Blaseofen*, or *Blauofen*. The furnaces were at first

exactly like the *Stückofen*, and the name referred to the product, not to the construction. Eventually cast iron was virtually the only direct product; and, as is the case at the present time, it was obtained in the blast-furnace. The *blast-furnace* came to be called the *Hochofen* in Germany, and *le haut fourneau* in France. According to J. M. Swank,[6] the blast-furnace originated in the Rhine provinces about the beginning of the fourteenth century, and in 1340 one was built at Marche-les-Dames, Belgium. The evolution of the blast-furnace in Styria was described by J. Arduino, L. Beck, J. M. Bineau, L. Bittner, J. J. Ferber, H. Frontault, G. Göth, O. Johannsen, F. Kupelwieser, A. H. Leobner, F. A. von Marcher, A. von Muchar, A. Müllner, F. Münichdorfer, V. Ignaz von Pantz and A. J. Atzl, I. Prandstetter, M. Robert, A. Schauenstein, and R. Schaur. Many others have written on the history of blast-furnaces, either in general or in reference to particular localities. According to A. Müllner, the iron industry has been active in Central Austria for over 2600 years, and occupied so important a position in the middle of the fifteenth century that England sent to Austria for teachers for her iron industry.

Just as crude metal was extracted from the ore by fire, so was it found that by another application of the same purifying agent the crude metal could be converted into malleable iron. In the modern method for extracting iron from its ores, cast iron is first produced, and this product is employed as a starting-point for the manufacture of iron and steel. What was formerly an accidental and abnormal defect is now the regular and normal product.

In the sixteenth century the ironworks in England were consuming the forests to make charcoal fuel at such a rate that it was feared that there would be a scarcity of wood for fuel and shipbuilding. According to J. Nicholl,[7] in the reign of Elizabeth Acts of Parliament were passed to restrict the use of timber as fuel in the manufacture of iron. A patent was granted to S. Sturtevant in 1611 by James I for the use of " sea-coale or pit-coale " in the extraction of iron, but the patent was " cancelled and made voyde by reason of his standing outlawed at the time of the grant." In 1613 his privileges were transferred to J. Rovenzon, but he did not make the use of this fuel a success ; and similar remarks apply to the patents of W. Gomeldon, F. de Blewston, and E. Jorden. About 1620, however, D. Dudley did succeed in substituting pit-coal for charcoal in the smelting of iron ; he obtained a patent for the process in 1619, and gave an account of his labours, but not the process, in his *Metallum martis*, published in 1665. Between 1652 and 1658 Oliver Cromwell granted patents to W. Astell and co-workers for the use of pit- or sea-coal as fuel in the blast-furnace, but both attempts also failed. It is thought, but not definitely known, that the success of D. Dudley was due to his using coke in place of raw coal. R. Plot mentions an unsuccessful attempt to smelt iron with coal in 1685. H. Powle described the smelting of iron with charcoal as fuel in blast-furnaces in the Forest of Dean, in 1676, and the subsequent conversion of the cast iron into malleable iron in an open-hearth finery using sea-coal as fuel ; J. Collier, and J. Sturdy described the process in use in Lancashire at the end of the seventeenth century. D. Dudley does allude to the making of char—according to T. Turner, that is coke—from sea-coal. The art was lost after the death of D. Dudley, so that in 1685 R. Plot said :

They have a way of charring the coal in all particulars the same as they do wood. The coal thus prepared they call *cokes*, which conceives as strong a heat almost as charcoal itself, and is fit for most uses, but for melting, fining, and refining of iron, which it cannot be brought to do, although attempted by the most skilful and curious artists.

About 1735, J. H. Darby tried to smelt iron with a mixture of raw coal and charcoal, but without success ; he then tried the use of coke made by treating pit-coal as charcoal burners treat wood, and succeeded. The substitution of coke for charcoal then grew apace. Only in very special circumstances is charcoal now employed—*e.g.* in out-of-the-way places where the output is small, timber cheap,

and coal dear; or where a specially pure metal is desired, as at Ulverston, Lancashire, described by W. J. MacAdam. Hence, the furnace charge employed in 1887 was virtually the same as that employed in 1738. D. H. Wood reviewed the history of iron-founding in the Midlands (England).

The subject was discussed by J. F. d'Aubuisson de Voisins, L. Bittner, G. Göth, S. L. Goodale and J. Speer, H. Illies, O. Johannsen, W. A. Lampadius, F. W. Lürmann, E. Mauer and W. Bischof, A. Müllner, F. Münichsdorfer, V. I. von Pantz and A. J. Atzl, I. Prandstetter, A. Schauenstein, C. Schinz, E. Vollhann, and H. Wedding.

With bituminous coal most of the hydrocarbon gases are given off before the reduction of the ore is accomplished, and accordingly they do very little chemical work in reducing the ore. Heat is required for the decomposition of the coal, so that the extra fuel consumption gives an enriched exit gas. Anthracite coal gives but a relatively small yield of hydrocarbon gases, and more nearly approaches coke in this respect. Anthracite coal has been used in blast-furnaces in South Wales and in Eastern Pennsylvania. Attempts to melt iron by using a gaseous fuel—say natural gas—as a source of heat, while the reduction proper is effected by solid carbon were made in this direction by J. T. Wainwright, but the results were not satisfactory. Actually, in modern practice, at least 75 per cent. of the available energy in the solid fuel employed is utilized. Charcoal is still employed as a fuel in the production of the so-called Swedish iron, and the modern procedure was described by J. A. Leffler. The use of peat coke was discussed by I. I. Granikoff and M. A. Pavloff.

According to M. P. Rossigneux, when coke began to replace charcoal in the smelting of iron, the furnaces were low, of small capacity, and worked with a cold blast. A light, porous coke resembling charcoal was desirable, because in such furnaces the hard coke would descend to the level of the tuyères, suffering very little change. In taller furnaces, of large capacity, worked with a hot blast, a hard, compact coke is needed in order to resist the weight of the heavy furnace charge. The density of the coke is greater the higher the coking temp., and the more dense the coke the less the fuel consumption, since less carbon is attacked by the carbon dioxide of the furnace gases. This was demonstrated by I. L. Bell. The blast-furnace coke must be strong enough to sustain without crushing the burden in the furnace; it must be porous enough to allow it to be penetrated by the hot blast; and it should burn with very little ash. The properties of good blast-furnace coke were discussed by S. Weill,[8] J. H. Darby, C. L. Bell, D. A. Louis, G. D. Cochrane, etc.

The substitution of coke for charcoal in the smelting of iron rendered necessary blowing machines of increasing power, and the introduction of steam power enabled engineers readily to cope with the demands of the iron smelters. This subject was discussed by C. J. B. Karsten,[9] J. Percy, D. E. Roberts, A. von Ihering, J. Kitson, E. Baur, A. Greiner, R. H. Rice, etc. In 1828, J. B. Neilson patented the use of the hot blast, and J. Percy said that " the use of the hot blast greatly cheapened the production of iron, and it is thus to be regarded as one of the most important improvements ever made in metallurgy." A few years later, in 1835, virtually every ironworks in Scotland was using the hot blast. According to E. Baur, and E. Herzog, A. C. W. F. von Faber du Faur utilized the hot blast in 1832. J. B. Neilson's invention, said H. Marten, appeared directly to contradict general experience, because all furnace managers agreed that the produce per furnace was more in winter than in summer, and hence it was concluded that the colder the blast the better the yield. Attempts were even made to cool the blast in summer by passing it over cold water, but a result contrary to expectation was observed. The conclusion was shown by H. Marten, and J. Percy to ignore two vital factors : (i) the air in summer is much more humid than it is in winter; and (ii) in hot weather the blowing engines will deliver a smaller weight of oxygen in a given time, unless they are worked at a faster speed.

The moisture in the gas was thought at one time to be advantageous, because the hydrogen formed by the dissociation of the steam is so powerful a reducing agent; but I. L. Bell showed that no advantage is obtained by raising the moisture content of the blast. W. H. Fryer, on the contrary, showed that the desiccation of the blast would increase the production, and decrease the fuel costs. J. Gayley proposed to freeze out the moisture by an ammonia refrigeration apparatus. The subject was discussed by C. A. Meissner, B. Osann, E. H. Lewis, F. Krull, E. Jantzen, W. Mathesius, J. B. Miles, N. M. Langdon, M. Drees, E. S. Cook, C. Aldendorff, J. Vajk, E. de M. Campbell, H. Bonte, W. Schmidhammer, A. Lindner, C. von Linde, L. Grabau, E. C. Heurteau, H. le Chatelier, J. E. Johnson, G. Jones, F. A. Daubiné and E. V. Roy, W. McConnachie, and J. von Ehrenwerth. The last-named showed that the advantage of drying the blast is greater the lower the temp. of the blast, and the higher the temp. of the waste gases at which the furnace previously worked. The use of oxygen in the dry blast was discussed by A. Brunighaus, F. W. Davis, M. Derclaye, J. Seigle, R. Schenck, H. Blome, G. Trasenster, and C. A. Edwards.

The hot blast was discussed by H. Marten, T. Clark, L. F. Gjers and J. H. Harrison, W. McConnachie, F. T. Merbach, J. Percy, W. Truran, D. Mushet, I. L. Bell, C. Cochrane, etc. The methods of heating the hot blast employed by J. B. Neilson were described by H. Marten. In 1833, A. C. W. F. von Faber du Faur invented a hot-blast stove which was heated by the combustion of the waste gases from the blast-furnace; but the method was not successful until applied by J. P. Budd in 1845. In 1860, E. A. Cowper applied the regenerative principle and burnt the waste gases in order to supply the necessary heat. There are many designs for the checker bricks for the hot stove, and also many modifications of the principle, discussed by T. Whitwell, T. Massicks, W. Crooke, B. J. Hall, E. Disdier, L. F. Gjers and J. H. Harrison, A. J. Boynton, W. Mathesius, S. G. Valentine, R. S. Moore, G. Jones, M. A. Pavloff, and A. Spannagel.

The ends of the pipes or tuyères employed for delivering the blast of air into the furnace rapidly deteriorate unless they are efficiently protected, and particularly so when a hot blast is employed. The term *tuyère* is often spelt *twyer*, and, according to R. Plot,[10] older and corrupt spellings are *tue-iron*, *tuiron*, and *tuarn*. J. Percy said that the protection of the tuyère by cooling it with water was first applied by Mr. Condie, shortly after the introduction of the hot blast. In this tuyère, generally called the *Scotch tuyère*, a wrought-iron pipe, through which cold water circulates, is embedded and coiled about a short, hollow, conical nozzle of cast iron. Numerous modifications of the principle have been described by F. H. Lloyd, T. W. Plum, H. Wedding, H. Pilkington, A. K. Rees, J. E. Stead, J. S. Hollings, F. L. Grammer, etc.

There are differences of opinion as to the most economical size and shape of the blast-furnace; and there are numerous descriptions of the blast-furnaces in different works available.[11] The subject is also discussed in many special books. There are also many labour-saving devices in connection with the mechanical handling of materials—conveying charges to the top of the blast-furnace, its introduction to the hoppers, and transfer to the furnace itself.

Ores can sometimes be worked in the blast-furnace without any preliminary treatment; in other cases the ore must be subjected to some preparatory process. Hand-picking to separate earthy and shaly matters may suffice; in some cases it is necessary to crush the ore into pieces the size of an egg. The sizing of the ore depends on its nature. A porous ore, for instance, can be used in larger lumps than a dense, compact ore, since it is more readily penetrated by the reducing gases. Systems of concentrating the ore can be employed only in special cases, on account of their cost. In some places the magnetic iron sands or tailings are washed by hand, but only on a moderate scale. Ore-washing in some of the United States works has been described by G. R. Johnson,[12] M. F. Ortin, and S. C. McLanahan. The concentration of ores by magnetic separators was proposed by A. Chenot[13] in 1854, and the electromagnetic and electrostatic separation has been discussed

by H. C. McNeill, H. Louis, W. A. Anthony, C. Jones, G. Prus, H. Wedding, T. Turner, etc.

Hæmatite ore was once concentrated at Norburg, Sweden, by screening the crushed ore, which was then graded, and the fines were briquetted with about 10 per cent. of lime before smelting.[14] Finely-divided ores have also been briquetted with tarry matters. W. Hutchinson and F. W. Harbord [15] proposed incorporating fine ores with molten blast-furnace slag. Ores in a fine state of subdivision are not suited for smelting in the ordinary blast-furnace because of the resistance they offer to the passage of the blast. Finely-divided ores are best smelted in blast-furnaces which are not very tall, and only a low-press. blast is employed. This subject was discussed by H. Louis, J. Gayley, E. Moffart, A. Thielen, etc.

In some cases the ore is weathered in heaps for months or years. The hard shale of argillaceous ironstone so treated crumbles to powder, and allows the iron ore to be separated by hand-picking. Certain sulphureous ores may also have their pyrites oxidized to sulphate and so washed away. Hydrated ores may be calcined or roasted to drive off water of hydration; carbonate ores, to drive off carbon dioxide; sulphide ores, to convert sulphides to oxides, and so eliminate the sulphur—at the same time some arsenic may be driven off; ferrous ores, to convert ferrous to ferric oxide with ferrous ores liable to form too fusible a slag, which rapidly attacks the furnace lining; and carbonaceous ores, like the black band ores, to drive off carbonaceous matter, which prevents a proper fusion of the materials in the blast-furnace. The subject was discussed by S. G. Valentine.[16] The roasting or calcination may be performed in open heaps or in special kilns.

The blast-furnace is a long cylindrical shaft fed at the top with ore, fuel, and flux, and supplied with the air necessary for the combustion of the fuel at the bottom. The function of the blast-furnace is to reduce the iron oxides to the metallic state, and at the same time convert the impurities into a fusible slag. Both molten iron and slag are discharged at the bottom of the furnace, whilst the waste gases pass away at the top. The materials employed in the blast-furnace charge are (i) the iron ore, containing essentially ferric oxide, (ii) the flux—generally limestone, and (iii) the fuel—charcoal or coke. A mixture of these materials is continually introduced at the top so that the interior is kept nearly full, while slag, or *cinder*, and cast iron accumulate in a molten state in the hearth at the bottom. The slag or cinder flows out over the dam, while the molten iron accumulates below. The iron is allowed to escape at intervals through the tapping hole. The solid contents of the furnace are gradually and continuously descending, while air blown in through the tuyères ascends to the top and is carried away in pipes as blast-furnace gas. The oxygen of the air impinges on the incandescent fuel, where it burns to carbon dioxide; this is immediately reduced to carbon monoxide. The ferric oxide is reduced partly by the carbon monoxide and partly by the carbon to form metallic iron. Higher up, the limestone is decomposed into carbon dioxide and calcium oxide. The temp. of the furnace is greatest near the tuyères, where the maximum combustion occurs, and decreases as the distance upwards increases. The reduced iron near the lower part of the furnace becomes highly carburized, and forms cast iron, which melts and trickles down to the hearth. The iron ore contains more or less impurities—silica, alumina, etc.—and the ash of the fuel contains more or less earthy matters. The iron is associated with the earthy, and other impurities whose nature is such that usually they readily fuse when they have entered into combination with lime. The limestone of the charge "draws" some silicon, sulphur, manganese, and alumina—but not phosphorus —from the melting iron. There is thus formed a frothy slag. Nearly all the phosphorus, much of the sulphur, three-quarters of the manganese, and some silicon remain with the molten iron. The molten slag trickles down to the hearth, and helps to protect the surface of the molten metal from any decarburization under the influence of the oxidizing blast.

The weight of materials entering the blast-furnace is from seven to nine times

the weight of the iron produced, and more than half the weight of materials entering the furnace is atm. air supplied by its blast. No solids are formed in the furnace working under normal conditions, since all the solids charged into the furnace are converted into molten slag and molten iron. The charge and products per ton of iron are approximately :

The following description (Fig. 14) of the blast-furnace of one of the largest steel plants in the United States, namely, that at Gary, on the southern shore of
FIG. 14.—Blast-Furnace in Circuit with Four Hot-Blast Stoves.

Lake Michigan, is based on that given by J. B. Walker.[17] The height of the blast-furnace is 90 ft., and the diameter 25 ft. It makes 550 tons of iron every 24 hrs. It is built of steel, like a large upright steam boiler, and is lined with firebricks. The lower and hottest portion is surrounded with hollow bronze bricks filled with rapidly flowing water to keep them cool. The blast passes up through 1500 tons of *burden*, which is at first arranged in alternate layers of ore, coke, and limestone, put in at the top so as to be porous enough to allow a free passage for the ascending gases driven upwards by the blast. The coke, ore, and limestone from the store

bins are carried by electrically operated lorries to the furnace skip, of which there are two to each furnace. The skips run up an inclined railway to the charging platform at the top of the blast-furnace. Each trip of a skip is made in 60 seconds, and its average load is 7000 lbs. of ore, 6000 lbs. of limestone, and 3600 lbs. of coke. On its arrival at the top of the furnace the skip automatically discharges its load into a hopper. Within the furnace are two cones. The contents of the skip fall upon the first cone or bell, A, which is then lowered so that the materials fall on the second or lower cone, B. The upper cone, A, is then elevated to seal the exit, and the lower cone, B, is lowered so as to discharge the materials into the furnace. This arrangement prevents any escape of the furnace gases.

The furnace once started is kept going continuously until repairs are necessary. Some furnaces have a record of several years' continuous operation. The temp. near the top is about 200°. The chemical action of the up-rushing blast of gas is to remove about 90 per cent. of the oxygen in the ore and transform it into particles of finely-divided spongy iron, which retain their shape as the charge descends until the iron is melted. The temp. of the charge increases as it descends, and at about 430° the spongy iron begins to take up carbon from the coke. There is an opposing chemical action tending to remove carbon from the iron. The iron takes up several times its own volume of carbon, and when the temp. of the descending charge has attained about 900° the iron sponge no longer expands. The iron with its dissolved carbon continues its descent and begins to melt. While these changes are going on, the limestone unites with the siliceous and aluminous constituents of the ore and with the ashes of the coke. The slag also melts and trickles down with the molten iron through the incandescent coke. The molten mixture collects at the bottom, so that the molten slag floats on the molten iron. The coke contains 88 per cent. of carbon, and the burning of the incandescent coke by the hot blast completes the fusion of iron and slag in the lower part of the furnace. The slag is drawn off at regular intervals from the *cinder notch*, C, and run into large ladles ; it is then hauled away to be crushed and utilized in the cement mills. The molten iron, containing about 3·5 or 4 per cent. of carbon, is drawn off separately from the *iron notch*, D, about every four hours. About 100 tons of pig-iron are obtained at one draw, which occupies about a quarter of an hour. The molten metal is transferred to the Bessemer converters or to the open-hearth furnaces to be transformed into steel. The blast is stopped for a moment to re-plug the notch. When the mass of material in the furnace is relieved of the supporting influence of the upward blast, it sinks a little.

The air required for combustion enters the furnace just above the hearth at press. of about 18 lbs. per sq. in., and then passes through a series of water-cooled tuyères. The hot furnace gases are led by a large pipe from the top of the furnace into a dust-catcher, and after being cleaned in a washer, they are passed through the hot-stoves. There are four hot-stoves to each furnace. The stoves are cylindrical plate-steel structures filled with a honeycomb of firebricks. As the gases enter two of the stoves a certain amount of air is fed in with them, and the burning gas, passing through the stoves, raises the firebricks inside to a high temp. When the proper heat is attained, the gases are deflected into an adjoining pair of stoves, while cold air from the blowing engines is made to enter at the bottom of the two stoves which have just been heated, and in passing through the honeycomb of firebrick the air takes up the heat previously given up by the furnace gases, and thus enters the blast-furnace at a high temp. Part of the heat carried off by the waste gases of the blast-furnace is thus returned. The two right-hand stoves in the diagram are represented as being heated by the burning gases, which are led in and ignited at the bottom, while the valves from the cold-air pipe are closed. At the top of these two stoves the valves opening to the hot-blast pipe are closed and the products of the burning gases pass into the atmosphere through the two smoke-stacks above the stoves. At the same time the valves opening from the cold-air duct at the bottom of the two left-hand stoves are open, while the corre-

sponding gas valves just above them are closed. The valves controlling the smoke-stacks are closed, and the valves opening to the hot-blast pipes are open.

The nature of the slag is controlled by the proportion of limestone which is added, and that, in turn, is determined by the character of the siliceous impurities associated with the ferric oxide in the iron ore. In some cases where the ore is non-aluminous a certain proportion of an aluminous ore analogous to bauxite, or an argillaceous ore, may be added.

This subject has been discussed by L. Blum,[18] G. Bontemps, O. Boudouard, O. Bowles, C. Braubach, G. Gredt, H. Wedding, S. E. Bretherton, C. Brisker, E. V. Britzke and co-workers, D. H. Brown, H. Burchartz and O. Bauer, R. Chauvenet, T. P. Colclough, A. L. Day and E. S. Shepherd, C. Dichmann, E. Diepschlag and H. Fliegenschmidt, E. Diepschlag and L. Treuheit, C. Dralle, K. Endell, E. Faust, A. L. Feild and co-workers, H. Fleissner, J. E. Fletcher, O. R. Foster, J. Fournet, O. Glaser, W. Grosse and W. Dinkler, L. Gruner, A. Guttmann, W. Harnickell and R. Durrer, A. Harpf and co-workers, F. Hartmann and A. Lange, J. F. L. Hausmann, E. A. Hersam, C. H. Herty and J. M. Gaines, G. Hilgenstock, E. Hollmann, W. G. Imhoff, C. E. Ireland, I. E. Johnson, J. L. Joseph and co-workers, C. J. B. Karsten, O. von Keil and P. Kettler, B. Kerl, E. Kochs and co-workers, B. Kosmann, T. Kuroda, A. Ledebur, R. S. McCaffery and co-workers, W. Mathesius, C. von Mayrhoffer, C. Méne, A. Michel, W. Mrazek, A. Mund and co-workers, B. Neumann, H. Passow, J. J. Porter, G. A. Rankin and F. E. Wright, R. Rieke, P. Rohland, J. Sarek, S. Schleicher, E. S. Shepherd and co-workers, O. Simmersbach, M. Simonis, L. G. Smith, M. Theusner, A. E. Uehling, A. de Vathaire, J. H. L. Vogt, H. Wedding, C. E. Wood and T. L. Joseph, and E. Zimmermann.

In some cases calcareous iron ores can be associated with siliceous ores to produce a self-fluxing mixture. The brown ores, known as minette, occurring in the Rhenish provinces are self-fluxing; while some Styrian ores are highly basic and require an acidic flux—like quartz, sand, etc. M. Paschke and E. Jung discussed slags for highly aluminous ores—e.g. those from Mayari. For acidic ores, where limestone is employed as a flux, there have been claims that it is more economical to employ caustic lime; that is, the limestone is calcined before it is introduced into the blast-furnace, instead of leaving the calcination of the limestone to be done in the furnace. The desulphurizing properties of limestone were discussed by T. Turner, J. E. Stead, etc. H. von Jüptner considered that a state of equilibrium is established in the partition of sulphur between the slag and the metal, and that the partition favours the slags with the highest basicity—vide infra, sulphur. T. Turner found that calcium sulphide tends to separate from the slag and to solidify last. R. Moldenke used fluorspar; and E. H. Saniter employed quicklime mixed with calcium chloride as desulphurizing agent; and E. J. Ball and A. Wingham found that fused potassium cyanide has a desulphurizing action. Magnesian limestones are sometimes used. R. S. McCaffery and co-workers discussed the viscosity of magnesian slags. F. C. Calvert applied a patent for the use of chlorine, or hydrochloric acid, or hypochlorite in the blast-furnace, introduced preferably in the form of sodium chloride along with the charge. The object was to remove phosphorus and sulphur, which united with sodium to form a slag. J. Percy reported no advantage accrued from the use of this nostrum. G. Kassel found the ferrous oxide combined as ferrous silicate is not reduced by the blast-furnace gases, and one function of strong bases like lime may be to drive the ferrous oxide from the silicate slag and so prevent undue losses. The proportion of ferrous oxide in the slags of the old Roman furnaces in the south of England was so great that the slags have been re-smelted for iron. Most of the oxide of manganese present in the ore is reduced and alloys with the iron—vide infra, manganese-iron alloys—but, according to C. H. Ridsdale, the manganese is partitioned between the iron and the slag, somewhat as follows :

Mn								
in iron	0–5	5–10	10–15	15–20	20–25	25–30	50–70	70–85 per cent.
in slag	1·0	1·5	2·0	2·5	3·0	3·5	4·0	4·5 per cent.

J. Percy has quoted the results of experiments made at Ekaterinburg, in the Urals; at Ougrée, in Belgium; and at Dowlais and Ebbw Vale, in Wales; and observations have also been made by L. Eck, C. Schinz, G. D. Cochrane, I. L. Bell,

C. Wood, etc. According to T. Turner, the advantages and disadvantages attending the use of quicklime are so evenly balanced that quicklime is not likely to displace limestone except when small furnaces are used, or where the gaseous products are abnormally great. R. H. Sweetser, and R. H. Lee discussed the use of barium oxide ; M. Paschke and E. Jung, alumina ; F. Petry, magnesia ; and R. M. Keeney, fluorspar. K. Iwase and M. Fukushima studied the influence of siliceous matters on the reducibility of iron ores. The adjustment of the furnace charge for particular ores has been discussed by W. C. Roberts-Austen, C. A. M. Bolling, H. C. Jenkins, A. Wingham, F. F. Amsden, W. Macfarlane, W. Mrazek, F. Toldt, B. Platz, L. Blum, F. Wittmann, S. P. Bjerregaard, etc. G. Lunde and T. von Fellenberg noted the occurrence of iodine in the slag.

In 1728, J. Payne,[19] and in 1813, J. Mander and co-workers patented processes for utilizing blast-furnace slag for making bricks, quarries, tiles, etc. The utilization of slag for levelling and reclaiming waste land, as road metal, as railway ballast, for sewage filter beds, for making bricks, paving blocks, cements, etc., has a large literature of its own. The waste heat of the slag has been utilized for evaporating pans,[20] and in the generation of low-press. steam. Slag may be granulated by allowing it to trickle into cold water, and if a jet of steam be blown into the molten slag, *slag-wool* is formed, and this is used as a non-inflammable material for packing.

Many collections of analyses of blast-furnace slags have been reported by B. Kerl,[21] A. Ledebur, J. Percy, A. von Kerpely, C. F. Rammelsberg, E. Riley, W. H. Miller, G. Lindauer, H. Pilkington, J. H. L. Vogt, I. L. Bell, C. E. Schafhäutl, B. Platz, F. Kupelwieser, H. Rathke, etc. With charcoal as fuel the composition ranges from about 45 to 65 per cent. silica, 5 to 10 per cent. alumina, and 30 to 45 per cent. bases. In A. Ledebur's collection the silica ranges from 40·95 to 66·90 ; the alumina, 3·33 to 8·70 ; the magnesia, 0·57 to 16·32 ; the lime, 17·00 to 31·23 ; the manganous oxide, 0·85 to 4·09 ; the ferrous oxide, 0·79 to 2·70 ; the potash and soda, 0·32 to 3·83 ; and the calcium sulphide, 0·38 to 2·10. While with coke as fuel the silica ranges from 30 to 35 per cent., the alumina, 10 to 15 per cent., and the bases, 50 to 55 per cent. In A. Ledebur's collection the silica ranges from 23·59 to 47·94 ; the alumina, 7·14 to 24·69 ; the magnesia, 1·09 to 18·30 ; the lime, 30·80 to 47·20 ; the manganous oxide, 0·19 to 4·91 ; the ferrous oxide, 0·21 to 1·60 ; the potash and soda, 0·50 to 2·35 ; and the calcium sulphide, 1·33 to 9·08. According to G. Lunde and T. von Fellenberg, all common varieties of iron and steel contain 0·1 to 1·10 mgrm. of iodine per kilogram—average 0·1 to 0·15 mgrm. per kgrm. P. Berthier, E. Riley, and J. Percy emphasize how rarely is phosphoric oxide found in blast-furnace slags, although the 0·15 to 3·51 per cent. found by E. Riley was considered to be exceptional, and was due to the imperfect reduction of the iron. C. C. von Leonhard found samples with high proportions of phosphoric acid. The reduction of phosphoric oxide to form iron phosphide was discussed by N. Kjellberg, and G. Hilgenstock. The reduction of some silicon which alloys with the iron as silicide was discussed by A. Lampen. H. Bansen investigated the conditions of the materials at the lower stages of their descent through the furnace.

Although the materials are introduced into the blast-furnace in layers, the layers are broken up as the charge descends. The way the materials are distributed in the descending charge was found by F. Brabant [22] to be dependent on the shape and size of the furnace, and more particularly on the diameter of the mouth and the diameter of the charging cone. The subject was also studied by I. L. Bell, T. L. Joseph and co-workers, I. Bohm, T. J. Ess, B. V. Vuistavkin and co-workers, E. C. Evans and co-workers, E. Cotel, A. Peters, J. R. Young and R. C. Irving, R. A. Hacking, S. P. Kinnay, A. Siegel, C. C. Furnas and T. L. Joseph, R. H. Richards and R. W. Lodge, and E. C. Pechin. A cone of relatively large diameter gives an accumulation of coarse material in the centre, so that the ascending gases pass more readily up the centre than up the sides, where the finer material tends to accumulate. If a very marked separation occurs, the finer ore may be imperfectly reduced, and the smelting is then irregular. If the

bell is relatively narrow, the centre is finer and the outside coarse, when the smelting is irregular and the furnace lining is unduly worn. L. E. Grüner found the solid charge descended at the rate of about 20 ins. per hour, but in some modern furnaces T. Turner said its rate of descent is not infrequently 5 ft. per hour. G. Bulle, J. Stöcker and G. Bulle, C. C. Furnas and T. L. Joseph, R. H. Sweetser, W. Lennings, H. Bansen, E. Bertram, S. P. Kinney, etc., studied the effect of variations in the grain-size of the charges.

Estimates of the *temperature* in different parts of the blast-furnace were made by J. J. Ebelmen [23] about 1844, and later by P. von Tunner and R. Richter, S. P. Kinney, G. Eichenberg, A. Wagner, F. Kupelwieser, M. Jungst, P. Rheinländer, H. Allen, L. Rinman, and L. Rinman and B. Fernquist. According to H. le Chatelier, the highest temp. of the blast-furnace is in front of the tuyères, and it is about 1930°, and the first part of the tappings of grey cast iron had a temp. of 1400°, while the last and hottest portions had a temp. of 1570°—Swedish white cast iron melts at 1135°, and grey cast iron at 1220°. Again, according to I. L. Bell, the waste gases from a modern blast-furnace burning coke vary from 150° to 270°; the lower temp. corresponds with the introduction of fresh ore. The greatest variations are due to irregularities in the charging. The temp. curve for a furnace 75 ft. high, indicated in Fig. 15, is based on the observations of F. Clements—*cf.* also Fig. 16.

FIG. 15. — Temperature Zones of Blast-Furnace.

According to L. E. Grüner, the average rate of ascent of the gases in the blast-furnace approximates about 20 ins. per second, but with some modern furnaces T. Turner said that the speed of ascent is much greater. Numerous analyses have been made of the gases emitted at the top of the blast-furnace, and also of the gases at different levels in the furnace. The division of the furnace into specific zones of reaction has been based on these analyses. There are, of course, no hard-and-fast lines of demarcation between these zones, but certain reactions are favoured in particular regions of temp. Reports on the composition of the gases have been discussed by R. Bunsen,[24] R. Bunsen and L. Playfair, J. J. Ebelmen, T. Scheerer and C. Langberg, J. Stoecker, G. Heine, J. J. Berzelius, L. Ledebur, W. van Vloten, A. Jaumain, B. Osann, L. E. Grüner, F. Kupelwieser and R. Schöffel, R. Schöffel, L. Rinman, L. Rinman and B. Fernquist, A. Tamm, F. W. Lürmann, E. Bellani, M. Levin and H. Niedt, W. Hawdon, H. von Jüptner, P. von Tunner, P. von Tunner and R. Richter, I. L. Bell, J. E. Stead, J. Percy, H. Wedding, P. Gredt, and C. Stöckmann. According to A. Ledebur, the following analyses may be regarded as typical of the exit gases :

FIG. 16.—The Changes of Temperature and of the Composition of the Gases at Different Levels in the Blast-Furnace.

		N_2	CO	CO_2	H_2	CH_4
Charcoal fuel	vol.	56·7–57·6	23·1–25·5	14·7–15·3	1·7–4·3	0·5–0·8

Coke fuel	vol.	59·0–62·8	23·5–31·0	5·3–13·8	0·1–2·1	0·4–2·2
	wt.	55·0–61·5	21·9–30·1	8·1–20·2	0·01–0·1	0·2–1·9

Observations on the distribution of the gases in the blast-furnace have been made by M. Levin and H. Niedt, H. Niedt, N. Metz, W. A. Schlesinger, M. Zyromsky,

S. P. Kinney and co-workers, C. Aldendorff, F. Lange, G. Eichenberg and P. Ober-hoffer, G. Bulle, F. Sauerwald, H. Lent, R. Franchot, H. Koppers, P. Reichardt, H. H. Meyer, F. Wust and P. Wolff, W. Lennings, and R. Schenck. The results of S. P. Kinney are summarized in Figs. 16 and 17.
FIG. 17.—Changes in the Composition of the Metal at Different Levels in the Blast-Furnace.

A little *hydrogen* is found in the gases in all parts of the furnace; it originates from the moisture in the air-blast and in the raw materials: $C + H_2O = CO + H_2$; and, according to N. Metz, $CO + H_2O = CO_2 + H_2$. According to W. Müller, the hydrogen begins to reduce iron oxides at about 277°. The subject was discussed by W. van Vloten, B. Osann, and W. Lennings. Not only methane, but, as shown by the analyses of R. Bunsen and L. Playfair, and others, unsaturated hydrocarbons may also be present. J. J. van Laar discussed the relation between the working temp. of the furnace and the temp. of the blast necessary for a given fuel consumption provided that no carbon dioxide is present in the exit gases.

Small quantities of *hydrogen sulphide* also occur in blast-furnace gases. G. Hilgenstock found that the sulphur content of the gas did not exceed 0·06 per cent. The subject was discussed by T. L. Joseph, H. Wedding, and F. Wüst and P. Wolff. The desulphurizing action of slags was discussed by L. Blum, R. Bolling, H. L. Diehl, F. Firmstone, O. R. Forster, C. Frick, H. Geiger, C. H. Herty, G. Hilgenstock, O. Johannsen, J. E. Johnson, T. L. Joseph and co-workers, A. Killing, S. P. Kinney, A. Ledebur, L. M. Lindemann, R. S. McCaffery and J. F. Oesterle, A. McCance, F. Muck, B. Osann, E. H. Saniter, R. Schäfer, E. Schulz, O. Simmersbach, G. J. Snelus, J. E. Stead, N. B. Wittmann, C. E. Wood and T. L. Joseph, and F. Wüst and P. Wolff—*vide infra*, the action of sulphur on iron. The action of *silicon* or silica in the blast-furnace was discussed by I. Bohm,[25] S. L. Goodale, H. C. Greenwood, H. Hanemann, F. Lange, A. Ledebur, H. H. Meyer, G. Tammann and G. Bätz, H. von Wartenberg, F. Wüst, and F. Wüst and A. Schüller—*vide infra*, the action of silicon on iron. The behaviour of *titanium* in the blast-furnace was discussed by E. Bahlsen,[26] R. Durrer, J. Head, J. A. Heskett, J. F. Kemp, A. J. Rossi, O. Simmersbach, and O. Vogel—*vide infra*, the action of titanium on iron. The behaviour of phosphorus was discussed by I. Bohm,[27] W. Mathesius, H. H. Meyer, S. Stein, W. van Vloten, and F. Wüst—*vide infra*, the action of phosphorus on iron. Blast-furnace gases may contain varying quantities of *ammonia*; and G. Hilgenstock observed 0·06 grm. of ammonia per cubic metre of gas. A. E. Fletcher, H. Allen, F. W. Paul, and A. Gillespie discussed the recovery of tar and ammonia from blast-furnace gases.

R. Bunsen and L. Playfair [28] observed 1·34 per cent. of cyanogen in the lower part of a blast-furnace; H. Wedding thought that some mistake had been made, but W. Haufe and H. von Schwarze observed that cyanogen may be formed under the conditions which prevailed in the blast-furnace. In 1826, P. Berthier observed impure potassium carbonate in the hottest part of a blast-furnace at Merthyr Tydvil, and he inferred that it was derived from the ironstone employed. Possibly the substance collected by P. Berthier also contained cyanate, but not suspecting its presence, he failed to detect it. K. Jurisch noted the occurrence of hydrogen cyanide in blast-furnace gases. M. Desfosses observed that potassium cyanide is readily formed when nitrogen is passed over charcoal at a red-heat—the alkali, of course, was present as an integral part of the charcoal. G. Townes, and W. Hempel have confirmed this observation. J. Dawes obtained a patent for collecting potassium cyanide from iron-smelting furnaces by the introduction of a pipe near the tuyères of the furnace. J. C. L. Zinken and C. Bromeis, H. von Jüptner,

C. J. A. Scheerer, J. Müller, L. Eck, A. Gillespie, H. Braune, A. K. von Kerpely, W. McConnachie, C. A. Meissner, C. Catlett, R. Franchot, F. Lange, S. P. Kinney, A. Lefebvre, S. P. Kinney and E. W. Guernsey, W. Haufe and H. von Schwarze, R. Peters, and J. Redtenbacher discussed the occurrence of potassium cyanide in iron-smelting furnaces ; R. Bunsen and L. Playfair collected a considerable quantity of potassium cyanide from a blast-furnace at Alfreton. W. C. Roberts-Austen discussed the part possibly played by cyanides in the reduction of the ore ; J. Percy, and I. L. Bell consider that this is very small. H. Braune, and H. le Chatelier emphasized the fact that the formation of too much cyanide in the lower part of the furnace lowers the quality of the product, since nitrogen is absorbed by the iron from cyanides, but not from atm. air—*vide* nitrogen and iron. H. Kinder showed that besides being derived from the decomposition of carbon monoxide, the carbon found in the refractory linings of bricks may be due to the presence of cyanates of alkali metals in coke and ore : $K_2CO_3+N_2+4C=2KCN+3CO$, and $KCN+CO_2=KCNO+CO$; and with steam, and carbon dioxide, $2KCNO+CO_2+H_2O=K_2CO_3+2HCN+O_2$; and the latter in contact with particles of iron in the brick furnishes carbon, hydrogen, and nitrogen. These results were discussed by H. Ditz. F. W. Lürmann found that the alkali cyanides also act deleteriously on the linings of blast-furnaces.

The furnace gas carries along with it a fine flue-dust, which settles along the track of the gases as a white or yellowish-white powder. Numerous analyses have been reported by E. Ebermayer,[29] B. H. Thwaite, B. Kerl, J. Pattinson, P. von Tunner, A. von Kerpely, A. Engelhardt, G. Leuchs, H. Wedding, J. Percy, F. W. Lürmann, A. Ledebur, R. M. Colles, V. le Vrärier, W. B. Phillips, C. Pradel, and C. F. Rammelsberg. J. Percy quoted the analysis :

CaSO$_4$	MnO	CaO	MgO	K$_2$O	Al$_2$O$_3$	Fe$_2$O$_3$	SiO$_2$
4·42	1·77	2·30	1·13	1·80	8·43	47·05	30·33 per cent.

This is of no particular use. Sometimes, however, a relatively large proportion of potash salt is present, which can be removed by lixiviation with water. The following is quoted by A. Ledebur :

NH$_4$CyS	NaCl	KCl	MgCl$_2$	NH$_4$Cl	FeCl$_2$	MnCl$_2$	CaSO$_4$	K$_2$SO$_4$	SiO$_2$	Fe$_2$O$_3$	H$_2$O
0·69	13·02	19·26	10·95	6·59	0·54	0·10	5·27	31·14	0·64	1·47	9·92 per cent.

C. Bolin found a grey material in a blast-furnace at Eisenerz with constituents corresponding with :

KCy	KOCy	KCl	K$_2$CO$_3$	Na$_2$CO$_3$	Insoluble
26·52	2·09	2·83	40·59	10·72	17·36 per cent.

E. Priwoznik found that dust of a blast-furnace of the Austrian Alpine Co. contained :

KCy	KOCy	KSCy	K$_4$FeCy$_6$	Fe	Total K
0·08	0·69	0·24	7·86	6·86	35·29 per cent.
0·003	0·03	0·01	0·42	26·05	6·61

The occurrence of potassium salts in the flue-dust of blast-furnaces has been discussed—**2. 20, 5.**

The collection of analyses by F. W. Lürmann shows wide variations, and there may be present, in addition, sulphides or oxides of tin, lead, zinc, copper, silver, aluminium, antimony, thallium, manganese, iron, calcium, and magnesium ; also chlorides, sulphur, and carbonaceous matters. C. H. Lündström reported bismuth in the blast-furnaces at Finshytte ; L. Blum, J. J. Porter, M. Paschke, and F. W. Lürmann, zinc oxide ; I. A. Baar, I. L. Bell, F. Bicheroux, I. Bohm, W. D. Brown, F. W. Davis, M. Derclaye, J. E. Fletcher, R. Forsythe, L. Gruner, O. F. Hudson, J. E. Johnson, H. von Jüptner, A. Korevaar, A. Ledebur, R. Lorenz, W. Mathesius, H. H. Meyer, M. von Schwarz, A. H. Sexton, O. Simmersbach, B. Stoughton, H. Thaler, and T. Turner, manganese oxide ; W. Heike, lead and copper ; A. Ledebur, silver ; R. von Seth, and O. Vogel, vanadium ; E. D. Campbell,

copper, nickel, and cobalt; J. Pattinson and J. E. Stead, W. Mathesius, and O. Simmersbach, arsenic; A. Ledebur, antimony; and L. Blum, chlorides.

The recovery of the potassium salts from blast-furnace gases was discussed 2. 20, 4. The cleaning of the gas from dust is a problem in chemical engineering; and so also is the utilization of the waste-gas as a gaseous fuel. As an example of what can be done the following, according to J. B. Walker, represents the practice at Gary:

Part of the " waste gases " poured out of the blast furnace are employed for heating the hot stoves; for raising steam in batteries of boilers; for operating gas engines for running the furnace blowers; and also other gas engines for operating generators for the supply of power and light. The twelve blast furnaces at Gary produce 40,300,000 c. ft. of gas every hour. Of this amount 30 per cent. is used in heating the hot stoves; 7·5 per cent. is used in the steam-power plant; 2·5 per cent. is used in the primary washers for the hot-blast stoves, and in the secondary washers to clean the gas before it passes to the gas holders; 15 per cent. is used by the blowing engines; and the remaining 45 per cent. is available for running the gas engines in the electric power station. The purified gas has an average heating value of 90 B.T.U. per c. ft., and it is estimated that two and a half times as much can be derived from a given quantity of gas with gas engines as can be secured with boilers and steam engines. The blast furnace gas at Gary serves to operate fifty-seven 2500 to 3000 horse-power gas-driven generators and blowing engines.

As indicated above, the molten metal from the blast-furnace may be run directly into ladles and conveyed to converters or mixers to be made into steel; it may also be run into ladles and conveyed to machines where it is cast in iron moulds or chills. The old method of casting is to run the metal from the furnace to the depressions or moulds in the sand floor of the so-called pig-beds. The channel along which the iron ran to feed the moulds and the moulds bear a fanciful resemblance to a litter of sucking pigs; the runner was called the *sow*, and the iron in the moulds, *pigs*. Hence the term *pig-iron*. The pig-iron cast in sand moulds is also called

sand-cast pig, and that cast in metal moulds or chills is called *chill-cast pig*, and where machine casting is employed, *machine-cast pig*. The rate of cooling of sand-cast pig is sufficiently constant to enable a trained eye to obtain a rough indication of the proportion of contained silicon from the appearance of the fractured surface. Thus, a grey open fracture indicates a high silicon content, whilst a white fracture corresponds with a low proportion of silicon. The appearance of the fracture also gives a rough indication of the proportions of free and combined carbon, in that a grey iron is high in free carbon and low in combined carbon, whilst a white iron is low in free carbon and high in

FIG. 18.—The Grading of Cleveland Pig-Iron.

combined carbon. The indications are not so reliable with pig-iron cast in iron moulds, where the cooling is faster and more irregular.

One way of classifying pig-iron is based on the relation of free or graphitic to combined carbon. If much of the carbon be "free," the iron is called **grey pig-iron**; and if much combined carbon be present, **white pig-iron**; intermediate varieties furnish **mottled pig-iron.** The following analyses will illustrate the difference between the three varieties of pig-iron:

	Grey	Mottled	White
Combined carbon	0·90	1·80	3·00 per cent.
Free carbon	2·8	1·40	0·10 per cent.

The grey and mottled varieties may be further subdivided. Pig-irons, too, are often graded according to their source, because certain districts work a specially pure or a specially foul ore, and this gives the iron from these districts characteristic properties—good or bad. Another system of classification is based on analysis. For example, T. Turner[30] represented the analyses of

different grades of Cleveland pig-irons by Fig. 18. The percentage of sulphur is multiplied by 5 for the sake of clarity. All the samples from the Forest of Dean contained traces of copper. Another system of classification is based according to use. These different forms of iron-carbon alloys with over 2 per cent. of carbon are also called **cast iron**—*vide infra*, nomenclature. Cast iron is not malleable, nor can it be welded. It is used for casting articles—stoves and ornamental iron—which with ordinary usage are not likely to be subjected to shocks. Cast iron is the starting-point for the manufacture of wrought iron and steel. The so-called *foundry iron* for remelting includes foundry pig, malleable-iron pig, and charcoal iron. Foundry iron usually has sulphur below 0·05 per cent., and manganese up to about 2·5 per cent. or even more, and silicon up to 3 per cent. or even more. H. Allen said that foundry iron is generally not so grey as Bessemer pig-iron, and that the limits of composition for average qualities are :

Free C	Combined C	Silicon	Sulphur	Phosphorus	Manganese
2·19–3·85	0·06–0·75	1·71–3·19	0·01–0·05	0·61–1·77	0·26–1·68 per cent.

According to H. Littlehales, the term *bloom* is the earliest known name for the mass of metal obtained by smelting iron ore. *Bloom* is mentioned in many documents of the Anglo-Saxon period, and it was in use for some centuries. In the fifteenth century the term *sow* was sometimes used in place of *bloom*; and just as in the fifteenth century *sow* ousted the term *bloom*, so in tne early part of the sixteenth century the term *pig* displaced the term *sow* for the lump of iron from the ore. The old casting bed consisted of a main channel with smaller channels at the side. It has been accordingly suggested that the casting of metal in the main channel was known as *sow*, and the castings in the smaller channels as *pigs*. Actually, however, documentary evidence makes it probable that the term *pig* properly belongs to one period and *sow* to another.

The pig-iron produced with charcoal as fuel is usually made in blast-furnaces of smaller dimensions than when coke is used, and the product is usually of a higher degree of purity than ordinary pig-irons. For instance, the limits of composition of six grades of Swedish pig-iron, made with charcoal, range from :

Free C	Combined C	Silicon	Sulphur	Phosphorus	Manganese
3·29–4·19	0·29–0·86	0·02–1·38	0·01–0·03	0·01–0·05	0·06–2·46 per cent.

W. Danielsen said that good Swedish charcoal iron has less than 1·25 per cent. of slag, and that the range of composition for :

	C	Mn	Si	P	S
Finished iron	0·02–0·06	tr.–0·10	0·02–0·04	0·04–0·07	0·005–0·010 per cent.
Melting bars	0·06–0·14	0·04–0·10	0·02–0·04	0·015–0·022	0·005–0·010 per cent.

Forge pig-iron for puddling, etc., has a higher proportion of combined and a smaller proportion of free carbon, and accordingly it has a whiter fracture. It is usually produced at a lower temp. than the greyer varieties of iron. The limits of composition for average qualities are :

Free C	Combined C	Silicon	Sulphur	Phosphorus	Manganese
1·75–2·97	0·33–0·89	0·99–3·75	0·04–0·34	0·04–3·05	0·06–2·25 per cent.

A still lower grade of pig-iron with a mottled fracture has the limits of composition varying between :

Free C	Combined C	Silicon	Sulphur	Phosphorus	Manganese
1·07–2·55	1·25–2·31	0·70–1·79	0·10–0·30	0·02–1·50	0·14–1·13 per cent.

whilst the lowest grade of ordinary classes of pig-iron is white in fracture and very brittle, with limits of composition varying between :

Free C	Combined C	Silicon	Sulphur	Phosphorus	Manganese
0 to 0·88	2·28–3·50	0·38–1·59	0·15–0·36	0·03–1·40	0·19–1·10 per cent.

The steel-making irons include the so-called Bessemer pig-iron for conversion into steel by the acid process. The composition of a grey Bessemer pig-iron was :

Free C	Combined C	Silicon	Sulphur	Phosphorus	Manganese
3·43	0·33	2·51	0·02	0·04	0·48 per cent.

The pig-iron used for the basic Bessemer process or the Thomas-Gilchrist process has sulphur below 0·2 per cent., silicon below 1 per cent., phosphorus 1·5 to 3·0 per cent., and manganese about 1·5 to 2·5 per cent. The so-called low phosphorus pig-iron, used for making steel with an extra small proportion of phosphorus, has under 2 per cent. of silicon, below 0·03 per cent. of sulphur, below 0·03 per cent. of phosphorus, and below 1 per cent. of manganese ; and basic pig-iron—white or mottled—has less than 1 per cent. of silicon, less than 0·05 per cent. of sulphur, less than 1 per cent. each of phosphorus and manganese. The so-called ferro-alloys include ferromanganese, ferrosilicon, silicon spiegels, etc. T. E. Holgate gave :

	Free C	Combined C	Silicon	Sulphur	Phosphorus	Manganese
Ferro-silicons	0·55-2·40	0·11-0·35	8·54-17·80	0·041-0·078	0·047-0·115	1·07-3·25 per cent.
Silicon-spiegels	0·33-1·13	0·29-1·85	10·74-15·94	—	0·074-0·095	19·64-24·36 per cent.
Ferro-manganese	4·27-6·31		0·11-1·12	---	0·078-0·175	8·11-87·92 per cent.

A. Kayser found 0·07 to 0·29 per cent. of calcium, and 0·03 to 0·38 per cent. of magnesium in pig-iron from Bilbao. A. Ledebur found in Hungarian pig-iron : total carbon, 3·500 per cent. ; Si, 1·480 ; P, 0·123 ; S, 0·007 ; Sb, 0·001 ; Sn, 0·003 ; Pb, 0·005 ; Cu, 0·265 ; Cr, 0·012 ; Ni, 0·041 ; Mn, 2·440 ; and Ti, 0·039 ; and in Upper Silesian pig-iron : total carbon, 2·518 per cent. ; Si, 0·292 ; P, 2·360 ; S, 0·117 ; As, 0·006 ; Sb, 0·001 ; Pb, 0·002 ; Cu, 0·099 ; Cr, 0·073 ; Ni, 0·016 ; Mn, 0·792 ; Ti, 0·056 ; Co, 0·011 ; and V, 0·072 ; A. Pourcel gave for a French pig-iron : C, 2·257 ; Si, 3·265 ; P, 0·459 ; S, 0·036 ; Mn, 0·388 ; Al, 0·028 ; Cr, 0·027 ; V, 0·012 ; Cu, 0·009 ; Ni, and Co, 0·035 ; As, 0·015 ; Sb, 0·011 ; Ca, 0·072 ; Mg, 0·100 ; and Ti, 0·025. W. N. Hartley and H. Ramage observed indium, gallium, thallium, and molybdenum in iron ores. Observations on the grading and composition of pig-irons were made by T. Turner, K. Daeves, G. L. Luetscher, E. Adamson, A. Pourcel, H. Pilkington, I. L. Bell, H. P. Tiemann, J. E. Johnson, E. A. Kebler, etc. G. Bätz discussed the extraction of iron pyrites from the ores.

In localities where carbonaceous fuel is costly and cheap water-power is available, it has been found possible to generate electricity and use it as a source of heat for smelting iron. There has been quite a number of methods suggested for the **electrical smelting of iron ores.** These are described in various books on electric furnaces.[31] The following description of the smelting plant near Domnarfvet, Sweden, was furnished me by Mr. Harold Almquist when visiting the plant in Sweden. He said : The essential difference between the electrical process and the blast-furnace process is that the fuel required for heating and melting in the blast-furnace is replaced by electrical energy. In the electric smelting-furnace only that quantity of charcoal or coke required for reducing the ore is charged into the furnace. No air is blown into the furnace, so that the combustion of the carbon can be effected only by the oxygen of the ore. The differences in design and operation between an ordinary blast-furnace and an electric smelting-furnace are due to these conditions. A section through the furnace is represented in Fig. 19. The shaft and hopper arrangements at the top are similar to those of a blast-furnace. The furnace can be charged in any convenient way. The lower part, or hearth, differs from that of an
FIG. 19.—Electric Smelting-Furnace.

ordinary blast-furnace. It consists of a large crucible the walls of which are connected with the shaft of the circular roof or arch. Four to eight electrodes are inserted in the arch, and they have a diameter of 60 to 70 cms., dependent on the capacity of the furnace. The current is brought to the electrodes by copper busbars so as to allow a load of 2 amps. per sq. mm. The high-tension lines outside are connected to switches, etc., in a high-tension switchroom behind the furnace, and thence coupled to transformers, which bring down the voltage to 60 or 100 volts. The transformers stand as near as possible to the furnace and are connected with the same by the busbars.

Gas is drawn from the furnace at the top of the shaft and cleaned in the usual way. Part of it is again blown into the furnace through tuyères placed around the upper part of the hearth mantle, thus directing the cold gas into the interspace formed between the arch and the incline of the furnace charge. A certain quantity of gas is therefore always circulating in the furnace. The proper circulation of the gas is a very important factor for the successful working of the furnace. The gas cools the roof and thereby increases its life; it also distributes the heat and ensures the progress of the chemical reactions evenly between hearth and shaft. The formation of gas in an electric furnace is naturally considerably less than in a blast-furnace where about three times as much carbon is burnt. The heat carried by the gas from the hearth up through the shaft, as well as its ability to produce chemical reactions, is therefore less in an electric furnace than in a blast-furnace. This is counterbalanced by the gas circulation. The carbon dioxide of the gas is immediately reduced to carbon monoxide, which higher up the shaft is again oxidized during the reduction of the ore.

The operation of the electric smelting-furnace is very sensitive and requires careful attention. For instance, the amount of carbon in the charge must be exactly adjusted to the oxygen of the ore. If too much carbon is used, the excess cannot be burnt off, and it accumulates in the hearth, thereby producing a " hot run." On the other hand, if insufficient carbon is employed, the reduction will be incomplete, and the furnace will " run cold."

The iron ore employed at Domnarfvet is the well-known Grängesberg magnetite mixed with some hæmatite and apatite; its composition is: Fe_3O_4, 65·00 per cent.; Fe_2O_3, 20·00; MnO, 0·30; MgO, 2·00; CaO, 4·00; Al_2O_3, 1·80; SiO_2, 4·50; and P_2O_5, 2·40. The pig-iron produced has the composition:

Carbon	Silicon	Manganese	Phosphorus	Sulphur
2·70	0·80	1·20	2·00	0·01 per cent.

The slag has the composition:

FeO	MnO	MgO	CaO	Al_2O_3	SiO_2	P_2O_5
1·00	2·90	10·00	42·00	7·10	34·00	0·90 per cent.

The analysis of the furnace gas is:

CO_2	CO	H_2	N	Hydrocarbons
20–25	60–65	10–15	1·0–1·5	The rest per cent.

The gas from the electric furnace is in consequence considerably richer than ordinary blast-furnace gas, and this is an appreciable item on the credit side of the electric furnace account. The excess of gas has been estimated at about 500 cubic metres per ton of pig-iron, and it can be utilized as a fuel in metallurgical furnaces, for heating boilers, etc.

The fuel or reducing agent in the electric smelting-furnace is charcoal. The difficulties with coke are its low electrical resistance and high density, and there is a tendency for it to graphitize on the high-temp. zone about the electrodes. The electric smelting-furnace can be used with good economy only when the electric power is cheap. If the price per kilowatt-year exceeds about £4, the other items in the production costs must be low if the electric furnaces are to compete with blast-furnaces using coke at the ordinary price.

G. Tammann and G. Bätz,[32] G. Tammann and C. F. Grevemeyer, G. Bogitch, F. Sauerwald, and G. Kassel studied the extraction of iron from silicate ores ; and the extraction of iron from silicates by the electrolysis of the fused ore has been discussed by F. Sauerwald and G. Neuendorff ; and from pyrites, by G. Ongaro, R. D. Pike and co-workers, F. A. Eustis, and M. Guédras.   J. Reese, C. Adams, M. Boistel, and S. L. Madorsky studied the manufacture of iron by the reduction of molten iron oxide by hydrogen.

§ 4. The Chemical Reactions in the Blast-Furnace, and in the Reduction of Iron Oxides

In general, the reactions in the blast-furnace, near the tuyères, involve the oxidation of carbon: $C+O_2=CO_2$; $2CO_2=2CO+O_2$; $2C+O_2=2CO$; for R. Bunsen and L. Playfair [1]—*vide supra*—found that the oxygen of the blast is burned in the immediate vicinity of the tuyères, forming carbon monoxide. As a result, no free oxygen or carbon dioxide occurs in the gases ascending from the hearth into the boshes. W. van Vloten's analyses correspond with :

Oxygen	Carbon dioxide	Carbon monoxide	Hydrogen	Nitrogen
0	0	34	2	64 per cent.

Higher up still, the ferric oxide is reduced by the carbon monoxide : Fe_2O_3+3CO $=2Fe+3CO_2+4\cdot6$ cals. There are thus two zones when heat is generated in the blast-furnace : (i) near the tuyères, where carbon is oxidized to the monoxide, and (ii) higher up, where the ferric oxide is reduced. I. L. Bell found that the relative proportions of carbon and oxygen in the gases, per 100 parts of nitrogen, at different heights above the tuyères, were :

Height	.	0	6	12	25	37	50	60	76·5 feet
Carbon	.	26·8	25·2	24·6	23·9	24·1	23·8	24·0	27·5
Oxygen	.	36·5	33·7	33·3	32·6	33·1	32·4	33·9	41·6

C. R. A. Wright emphasized that there is a complex play of reactions involving different oxides of iron, and carbon, and carbon monoxide and dioxide ; while E. Baur and A. Glässner showed that at atm. press. FeO and Fe_3O_4, carbon, CO, and CO_2, can exist side by side at 647°, and the three solids at 685° ; above 685° carbon and iron can exist together, and below 647° carbon and ferrosic oxide. Iron in contact with a gas rich in carbon monoxide below 647° is oxidized and carbon is deposited, while above 680° no carbon is deposited from the gas. C. Zix studied the deposition of carbon. The equilibrium conditions and the work of E. Baur and A. Glässner are discussed by P. Mahler.

According to L. Mond, the temp. of the blast-furnace is never low enough to permit the formation of iron carbonyls. There is also the endothermal decomposition of the limestone in the body of the furnace to be considered, when the temp. is between 566° and about 810°. At the high temp. in the vicinity of the tuyères there also occurs the reduction of silica : $SiO_2+2C=2CO+Si$; of manganous oxide : $MnO+C=Mn+CO$; and of phosphoric oxide : $P_2O_5+5C=5CO+2P$; all of which are favoured by the presence of iron, which alloys with the manganese, silicon, and phosphorus. These three reactions are of minor importance in the study of the equilibrium conditions in the furnace. G. Charpy and L. Jacqué found the barium and calcium sulphates begin to be reduced at 600°, and the process is rapid at 900° to 950°. Reduction by the metal alone results in the sulphurization of the iron. I. L. Bell showed that under ordinary conditions the part played by hydrogen in the reduction of iron ore is relatively unimportant ; and that from thermochemical principles the use of hydrogen or of water vapour, which would yield hydrogen by decomposition in the furnace, offers no particular advantage. The equilibrium conditions with hydrogen and the iron oxides are discussed below.

T. Turner showed that the theoretical minimum amount of carbon required to produce one unit of iron approximates :

Reduction of ferrric oxide . . .	4·84
Carbon required for generating heat .	0·30
Carburization of iron	0·60—Total 5·82 units

I. L. Bell, T. Turner, S. P. Kinney and co-workers, W. Mathesius, J. E. Johnson, A. Morette, P. Geimer, E. Maurer, N. Metz, H. Thaler, H. le Chatelier, M. Levin, E. Pierre, F. A. Kjellin, B. Osann, P. Anglès d'Auriac, M. Zyromsky, W. D. Brown, G. Tobin, W. Lennings, G. Eichenberg and P. Oberhoffer, W. G. Gillhausen, K. Hofmann, G. Godin, C. P. Linville, P. Farup, J. M. Clay, L. Lévêque, H. Riesenfeld, W. J. Foster, F. T. Sisco, B. Stålhane, W. McConnachie, F. Mulet, F. Logeling, H. von Jüptner, R. A. Hacking, F. Wüst, E. Richarme, H. Kamura, G. Rocour, E. A. Uehling, T. Weill, H. Mehner, A. Wagner and co-workers, J. Seigle, M. Derclaye, R. Franchot, J. Lilot, K. Mühlbradt, H. Bansen, P. Reichardt, R. H. Sweetser, A. Michel, I. Bohm, G. Bulle, A. Michel, P. H. Emmett, F. C. Howard, T. L. Joseph, H. H. Meyer, O. C. Ralston, E. C. Evans and F. J. Bailey, F. Clements, L. E. Gruner, F. Brabant, and many others have drawn up heat balance sheets of the blast-furnace.

Expressing the results in hundredweights or cwt. calories, H. Allen gave per ton of hot-blast pig-iron :

HEAT BALANCE OF BLAST-FURNACE PER TON OF IRON.

Combustion C to CO_2 . .	40,240	Reduction of iron . .	37,680
Combustion C to CO (less lime-		Carbon deposited from CO	1,800
stone effect) . . .	31,800	Evaporation water in coke	1,024
Heat introduced by blast .	12,289	Expulsion CO_2 from lime-	
		stone	3,345
Total heat supplied . .	84,329	Reduction CO_2 to CO	3,840
		Decomposition H_2O in blast	1,479
		Fusion of iron . . .	6,600
		Fusion of slag . . .	7,188
		Reduction silica . .	4,384
		[Heat appropriated by	
		furnace . . .	67,340]
		Escaping CO_2 . . .	1,385
		Escaping CO . . .	3,576
		Escaping hydrogen . .	30
		Escaping nitrogen . .	7,111
		Escaping water . .	1,673
		[Heat lost in escaping	
		gases . . .	13,775]
		Heat lost by tuyère water .	1,293
		Heat not utilized . .	16,989
		Total heat . . .	84,329

The subject was discussed by H. Bansen,[2] J. F. Barkley, W. A. Bone and co-workers, E. Bormann, W. D. Brown, G. Bulle, B. F. Burman, F. Clements, R. Durrer, G. Eichenberg and co-workers, E. C. Evans, E. C. Evans and E. J. Bailey, A. L. Feild, K. Feist, J. B. Fortune, C. C. Furnas, W. G. Gillhausen, L. Gruner, R. Hahn, H. P. Howland, T. C. Hutchinson, J. E. Johnson, A. Korevaar, F. Lange, O. O. Laudig, W. Lennings, M. Levin and J. Wesselmann, A. Liebreich, L. Mathesius, W. Mathesius, E. Maurer, M. A. Morette, K. Mühlbradt, B. Osann, A. K. Reese, P. Reichardt, J. W. Richards, P. H. Royster and co-workers, R. Schenck, O. Simmersbach, H. Thaler, G. Tobin, W. Trinks, P. W. Uhlmann, A. Wagner, A. Wagner and G. Bulle, H. Wedding, F. Werndl, H. E. Wright, and F. Wüst.

The system : Fe-O-H.—For the reduction of ferric oxide, Fe_2O_3, to ferrosic oxide, Fe_3O_4, and to iron, *vide infra*. In the light of later knowledge the observations of J. L. Gay-Lussac,[3] H. V. Regnault, H. Debray, and W. Müller indicate that the reaction between steam and iron is a reversible process. H. St. C. Deville studied the application of the law of mass action in the equilibrium between ferrosic oxide, iron, steam, and hydrogen : $Fe_3O_4+4H_2 \rightleftharpoons 4H_2O+3Fe$. The equilibrium constant can be written $K_3=[H_2O]/[H_2]$, where it is assumed that the solid phase is a mixture of Fe and Fe_3O_4. Analogous results were obtained by approaching the state of equilibrium from both directions. The values of K_3 derived from these experiments are :

	200°	265°	360°	440°	670°	920°
K_3. .	0·0491	0·0688	0·1188	0·1758	0·5410	0·6590

If p_1 be the press. of the water vapour, and p_2 that of the hydrogen, the values for the constant K_3 will be :

			200°			400°	
p_1	.	.	4·6	9·7		4·6	10·1
p_2	.	.	95·9	195·3		25·8	57·9
K_3	.	.	0·048	0·049		0·178	0·174

Hence, if water vapour be passed over iron, the ratio p_1/p_2 is greater than the constant $K_3=p_1/p_2$, and chemical change will go on until the iron is converted into oxide ; when hydrogen is passed over the oxide, the ratio p_1/p_2 is less than the above constant, and consequently the oxide will be reduced. At about 1500°, K_3 is nearly unity, so that if a mixture of equal proportions of water vapour and hydrogen be passed over either the metals or the oxide at this temp., no chemical change will occur. G. Preuner repeated the experiments under somewhat similar conditions and obtained $K_3=0.687$ at 900° ; 0·781 at 1025° ; and 0·860 at 1150°. Observations were also made by G. Chaudron, L. Wöhler and W. Prager, G. Gallo, L. Wöhler and O. Balz, W. Krings and J. Kempkens, and E. Schreiner and F. B. Grimnes. In the early experiments there was no assurance what particular oxide (or oxides) was concerned in the reaction. H. St. C. Deville at first supposed that the solid phase is Fe_4O_5 ; G. Preuner, a mixture of Fe and Fe_3O_4 ; and O. Sackur, an oxide between Fe and FeO. E. Schreiner and F. B. Grimnes obtained results in good agreement with the assumed reaction : $Fe+H_2O{\rightleftharpoons}FeO+H_2$; they found discrepancies between their results obtained at higher temp. and those of other workers. The thermodynamical values of the equilibrium constant are higher than the observed results, and this is attributed to the formation of solid soln. between iron and ferrous oxide. G. Chaudron showed that in all probability the ferrous oxide formed at a high temp. is decomposed : $4FeO=Fe+Fe_3O_4$ below 570°, so that under these conditions it is assumed that ferrosic oxide is the oxide in equilibrium with iron. At 570° the three solids Fe, FeO, and Fe_3O_4 are in equilibrium ; and above that temp. the equilibrium curve has two branches, corresponding with the equilibria : $Fe+H_2O{\rightleftharpoons}FeO+H_2$ and $3FeO+H_2O{\rightleftharpoons}Fe_3O_4+H_2$; below 570° there is only one system involved : $4FeO=Fe_3O_4+Fe$. This subject was discussed by A. Smits and J. M. Bijvoet—vide infra, ferric oxide. P. P. Fedotéeff and T. N. Petrenko found that the product of the oxidation of iron by steam at 1000° to 1100° changes continuously in composition from ferrous oxide to ferrosic oxide, although at any given time only one solid phase is present. It thus seems that both isomorphous mixtures and solid soln. of the oxides must be formed. The first effect of the steam is probably to form a layer of ferrous oxide on the surface of the metal, and this is quickly oxidized to ferrosic oxide, which is reduced to the ferrous state again by the neighbouring metal, after which oxidation again occurs, and so on. E. D. Eastman and R. M. Evans measured the equilibrium constants $[H_2O]/[H_2]$, namely K_1 for the system involving Fe : FeO, and K_2 for the system involving FeO : Fe_3O_4. The results were :

		700°	750°	800°	850°	900°	950°	1000°
K_1	.	0·584	0·645	0·706	0·765	0·822	0·879	0·937
K_2	.	1·45	2·11	2·98	4·16	5·50	7·08	9·12

These corresponding curves, Fig. 22, intersect near 570°, below which temp. ferrous oxide is unstable with respect to ferrosic oxide and iron. Fig. 20 shows the percentage of hydrogen with respect to these equilibria at different temp. G. Chaudron's values for the equilibrium constants are not in close agreement with those of other workers, excepting perhaps those of J. B. Ferguson. The observations of L. Wöhler and co-workers, K. Hofmann, K. M. Tigerschiöld, A. McCance, W. Biltz and H. Müller, S. L. Madorsky, W. E. Jominy and D. W. Murphy, W. P. Fishel and J. F. Wooddell, B. Neumann and G. Köhler, J. B. Ferguson, C. H. Herty, P. H. Emmett and J. F. Schultz, J. Thibeau, P. Faúp, E. Schreiner and F. B. Grimnes, P. van Groningen, and E. D. Eastman and R. M. Evans are in very

fair agreement for the values of the equilibrium constants. The thermal value of the reaction : $Fe+H_2O=FeO+H_2$, calculated by G. Chaudron, is 6·6 Cals. per mol at room temp. and 3·8 Cals. at 700° ; K. M. Tigerschiöld gave 9·0 Cals. at 17° ; L. Wöhler and R. Günther obtained 3·9 Cals., and P. van Groningen, 4·1 Cals. The thermal value of the reaction : $3FeO+H_2O$ $=Fe_3O_4+H_2$, calculated by G. Chaudron, is 19 Cals. per mol at room temp., and 11·6 at 650° ; K. M. Tigerschiöld gave 14·8 Cals. at 17° ; L. Wöhler and R. Günther, 14·4 Cals. ; and P. van Groningen, 15·7 Cals. The thermal value of the reaction : $3Fe+4H_2O=Fe_3O_4$ $+4H_2$, calculated by G. Chaudron, is 38·8 Cals. per mol at room temp., and 40 Cals. at 500° ; K. M. Tigerschiöld gave 41·8 Cals. at room temp. ; L. Wöhler and R. Günther, 37·2 Cals. ; and P. van Groningen, 28·0 Cals. K. M. Tigerschiöld calculated for the thermal value of the reaction : $3Fe_2O_3+H_2=2Fe_3O_4+H_2O$, 5450 to 8000 Cals. at 17°. The thermal value of the reaction : $3Fe+4H_2O=Fe_3O_4+4H_2O$, is 38,480 cals. at 17° when calculated from the heats of formation of ferrosic oxide and of water.

Fig. 20.—Chemical Equilibrium Curves.

G. Preuner's value, calculated from the equilibrium constants, is 11,900 cals. at 960°. A discussion of these reactions from other points of view by O. Hahn, F. Haber, C. H. Herty, F. S. Tritton and D. Hanson, etc., is resumed in connection with the ferrous and ferric oxides. The study of the equilibrium conditions gives no information on the speed of the reactions. For H. Kamura's observations on the rate of reduction of ferric oxide by hydrogen, *vide infra*. The subject was investigated by S. Mita, and B. Stälhane and T. Malmberg.

The system : Fe-O-C.—As early as 1869, I. L Bell [4] recognized the working of the mass law in the reduction of iron from its oxides by the furnace gases of the blast-furnace. He said : " Iron oxide can only be completely reduced by carbon monoxide when an excess of that gas is present." He also pointed out the complex nature of the conditions of equilibrium which must subsist between iron, carbon monoxide, carbon dioxide, carbon, and iron oxides of various kinds, at different temp. Observations were also made on the reaction by W. Müller, R. Akerman, R. Akerman and C. G. Särnström, A. Stansfield, H. le Chatelier, A. B. Kinzel and J. J. Egan, P. Pingault, E. Bauer, B. Stälhane and co-workers, H. Fleissner and F. Duftschmid, C. Svensson, G. Grönal, B. Kalling and G. Lilljekvist, S. Reiner and W. Feldmann, F. Glaser, R. H. Sweetser, H. Tholander, B. Kosmann, L. Mathesius, C. Schinz, J. Wiborgh, M. Mayer and J. Jakoby, K. Arndt and G. Schraube, H. Tutsya, F. E. Rhead and R. V. Wheeler, E. Terres and A. Pongracz, C. C. Furnas and G. G. Brown, E. Scheil and E. H. Schulz, R. Schenck, G. Bodländer, K. Stammer, P. Schützenberger, H. St. C. Deville, A. Ledebur, A. Guntz, L. E. Gruner, J. J. Ebelmen, L. Rinman and B. Fernquist, F. Kupelwieser and R. Schöffel, I. Bohm, W. G. Gillhausen, P. H. Royster and co-workers, H. H. Meyer, N. Metz, G. Bulle and W. Lennings, G. Bulle, G. Eichenberg and P. Oberhoffer, M. L. Becker, E. Jänecke, J. Klärding, H. Dünwald and C. Wagner, W. Krings, N. A. Kostuileff, and F. Wüst.

F. Wüst, W. P. Fishel and J. F. Wooddell observed higher proportions of carbon dioxide than correspond with the equilibrium value at 800° to 1100°. P. Farup discussed the catalytic action of iron ores in decomposing carbon monoxide. In the ternary system with carbon, oxygen, and iron, K. Iwase, and T. Watase said that there are the following systems to be considered : (1) Fe_2O_3+3CO $=2Fe+3CO_2$; (2) $Fe_2O_3+3C=3CO+2Fe$; (3) $3Fe_2O_3+CO=2Fe_3O_4+CO_2$; (4) $Fe_3O_4+CO=3FeO+CO_2$; (5) $Fe_3O_4+4CO=3Fe+4CO_2$; (6) $FeO+CO$ $=Fe+CO_2$; (7) $FeO+C=Fe+CO$; (8) $3FeO+5CO=Fe_3C+4CO_2$; and (9) $3Fe+2CO=Fe_3C+CO_2$. Reactions (2) and (7) are irreversible ; reactions (4) and (6) are incompatible with (5). I. Braithwaite noticed that at a dull red-heat
ferric oxide is completely transformed into ferrosic oxide by the action of carbon monoxide: $3Fe_2O_3+CO=2Fe_3O_4+CO_2$. W. A. Bone and co-workers obtained the results summarized in Fig. 21. With up to about 11 per cent. of deoxidation there is the irreversible reaction $3Fe_2O_3+CO\rightarrow2Fe_3O_4+CO_2$; with between 11 and about 30 per cent. deoxidation the reversible reaction $Fe_3O_4+CO\rightleftharpoons3FeO+CO_2$ occurs; and with between 30 and 85 per cent. deoxidation the reaction is $FeO+CO\rightleftharpoons CO_2+Fe$. In the blast-furnace, of course, above the region where the limestone decomposes, carbon dioxide is being poured into the gaseous system, with its consequent effect on the equilibrium relations of the reversible reactions.

E. Baur and A. Glässner measured the equilibrium constant in the reaction $FeO+CO\rightleftharpoons Fe+CO_2$, and obtained for $K_1=[CO]/[CO_2]$:

	550°	680°	750°	850°	900°
K_1 . .	1·78	1·44	1·56	2·12	2·51

The curve, Fig. 20, has a minimum, while for the reaction $Fe_3O_4+CO=3FeO+CO_2$ the curve has a maximum. They obtained for $K_2=[CO]/[CO_2]$:

	450°	550°	650°	750°	850°	950°
K_2 . .	0·852	0·786	0·587	0·439	0·351	0·299

The results when plotted furnish the curves in Fig. 21. The curves represent equilibrium lines in connection with the corresponding oxides and iron. According to
FIG. 21.—The Progress of the Step-by-Step Reduction of Ferric Oxide.
FIG. 22.—Equilibrium in Systems with Iron, Iron Oxides, and Carbon Monoxide and Dioxide.

H. W. B. Roozeboom, each system involves three components—Fe, C, and O—and three phases, two solids—Fe and FeO or FeO and Fe_3O_4, respectively—and a gas. Each system is therefore bivariant, so that, at any given temp., the mixture of gases exerts a definite press. and has a definite composition. The equilibrium curves in the system with the three components—Fe, C, and O—studied by E. Baur and A. Glässner thus divide the whole area of the diagram into three regions: A with iron; B with ferrous oxide; and C with ferrosic oxide. The results of E. Baur and A. Glässner indicate that above 600° equilibrium was probably attained, but the observed variations below this temp. make it doubtful if sufficient time had been allowed owing to the slowness of the reaction. The observations of R. Schenck and co-workers, H. J. van Royen, and M. Levin make it probable that the upper curve, Fig. 22, should be in the direction AB, Fig. 22, rather than in the direction AC. The minimum reported by E. Baur and A. Glässner at 650° has not been confirmed by other observers—E. Terres and A. Pongracz, R. Schenck and co-workers, E. D. Eastman, H. J. van Royen, M. Levin and H. Niedte, S. Hilpert and F. Beyer, G. Chaudron, F. E. C. Scheffer, and P. van Groningen. Rather do the curves assume the form of Fig. 21—vide ferrous oxide—and it is analogous to the curves deduced for the steam-iron equilibrium. G. Chaudron, and P. van Groningen place the quadruple point at 570°, and here iron and ferrous and ferrosic oxides can exist beside the

gas phase; below 570° the reaction proceeds: $Fe_3O_4+4CO \rightleftharpoons 3Fe+4CO_2$; and above 570°, in accord with $Fe_3O_4+CO \rightleftharpoons 3FeO+CO_2$, and $FeO+CO \rightleftharpoons Fe+CO_2$.

According to H. Semiller, expressing the concentrations of the gases in percentages, and the total pressure at equilibrium by p mm.:

	552°	556°	561°	596°	619°	651°	662°
[CO]	53·7	53·4	53·6	55·5	56·8	57·9	58·4
[CO$_2$]	46·3	46·6	46·4	44·5	43·2	42·1	41·6
p	129·7	136·9	142·2	296·4	411·3	570·9	662·0
K_1	1·160	1·146	1·155	1·247	1·315	1·375	1·404

The values of E. Baur and A. Glässner, R. Schenck and co-workers, M. Levin, H. J. van Royen, V. Falcke, E. Terres and A. Pongracz, G. Chaudron, and A. Matsubara were averaged by E. D. Eastman and R. M. Evans with the following results:

	600°	700°	750°	800°	850°	900°	950°	1000°
K_1	0·871	0·678	0·608	0·552	0·505	0·466	0·432	0·403
K_2	1·15	1·68	2·02	2·40	2·79	3·24	3·67	4·17

L. Wöhler and R. Günther obtained for the three constants log $K_1=-854T^{-1}$ [1] $+0\cdot666$; log $K_2=-3143T^{-1}+3\cdot398$; and log $K_3=-1480T^{-1}+1\cdot411$; and they calculated from G. Chaudron's data log $K_1=-742T^{-1}+0\cdot44$; log $K_2=-2632T^{-1}$ $+2\cdot68$; and log $K_3=-1510T^{-1}+1\cdot36$. P. van Groningen gave log $K_1=-897T^{-1}$ $+0\cdot68$; log $K_2=-3435T^{-1}+3\cdot67$; and log $K_3=-532T^{-1}+1\cdot42$. K. Hofmann calculated from E. D. Eastman's data with the steam and iron reaction log K_1 $=-954T^{-1}+0\cdot57$; and log $K_2=-2900T^{-1}+3\cdot15$; and from E. D. Eastman's data for the CO_2 and iron equilibrium, log $K_1=-834T^{-1}+0\cdot636$; and log $K_2=-3237T^{-1}$ $+3\cdot509$. L. Wöhler and O. Balz, and K. M. Tigerschiöld calculated values for the constant K_4 with Fe_3O_4 and Fe_2O_3 as the solid phases: $3Fe_2O_3+H_2=2Fe_3O_4+H_2O$ —a system also studied by P. van Groningen, and H. Kamura. For the $Fe \rightarrow FeO$ equilibrium—i.e. $FeO+CO \rightleftharpoons Fe+CO_2$—with $K_1=[CO_2]/[CO]$, E. D. Eastman gave log $K_1=949T^{-1}-1\cdot140$; A. McCance, log $K_1=675T^{-1}-0\cdot87$; K. Hofmann, log K_1 $=949T^{-1}-1\cdot140$; P. van Groningen, log $K_1=1000T^{-1}-1\cdot16$; K. M. Tigerschiöld, log $K_1=217\cdot7T^{-1}+0\cdot5$ log $T-0\cdot0006348(T-600)-1\cdot708$; and R. R. Garran, log $K_1=868T^{-1}-1\cdot055$; as well as log $K_1=4160T^{-1}+9\cdot51$ log $T-0\cdot00121T$ $-31\cdot680$. For the $FeO \rightarrow Fe_3O_4$ equilibrium—i.e. $Fe_3O_4+CO \rightleftharpoons 3FeO+CO_2$— with $K_2=[CO_2]/[CO]$, E. D. Eastman gave log $K_2=-1645T^{-1}+1\cdot925$; A. McCance, log $K_2=-1304T^{-1}+1\cdot68$; and log $K_2=-1304T^{-1}+1\cdot68$; K. Hofmann, log K_2 $=-1645T^{-1}+1\cdot935$; P. van Groningen, log $K_2=-1600T^{-1}+1\cdot92$; K. M. Tiger-schiöld, log $K_2=-715\cdot6T^{-1}+0\cdot5$ log $T-0\cdot000564(T-600)-0\cdot735$; and R. R. Garran, log $K_2=-1434T^{-1}+1\cdot723$, as well as log $K_2=-3440T^{-1}-7\cdot91$ log $T+0\cdot00161T+25\cdot860$. For the $Fe \rightarrow Fe_3O_4$ reaction—$Fe_3O_4+4CO \rightleftharpoons 3Fe+4CO_2$ —K. Hofmann gave log $K_3=261T^{-1}-0\cdot325$; and P. van Groningen, log K_3 $=354T^{-1}-0\cdot39$. K. M. Tigerschiöld observed that at 450°, $K_3=0\cdot91$, and at 500°, $0\cdot89$; and for the quadruple point, where there are the co-existing phases Fe, FeO, Fe_3O_4, and gas, he gave 534°; while A. McCance gave 503°, for here K_1 $=K_2=K_3=1$. According to I. Braithwaite, and R. Akerman and C. G. Särn-ström, the reaction $3Fe_2O_3+CO=2Fe_3O_4+CO_2$ is practically complete at a dull red-heat; and A. Matsubara showed that the reaction is irreversible, due, it is supposed, to the high dissociation press. of the ferric oxide. K. M. Tigerschiöld came to the same conclusion, but K. Iwase regarded the question as an open one. The reaction was also studied by H. Groebler and P. Oberhoffer.

R. R. Garran's curves are expressed in percentages; for the $FeO \rightarrow Fe_3O_4$ reaction:

	600°	700°	800°	900°	1000°	1100°	1200°	1300°
[CO]	43·7	35·3	28·2	22·4	18·1	14·8	15·5	—
[CO$_2$]	56·3	64·7	71·8	77·6	81·9	85·2	87·5	—

and for the $Fe \rightarrow FeO$ reaction:

	600°	700°	800°	900°	1000°	1100°	1200°	1300°
[CO] .	—	59·5	65·0	69·3	72·7	75·0	76·5	77·1
[CO₂] .	—	40·5	35·0	30·7	27·3	25·0	23·5	22·9

According to A. Smits and J. M. Bijvoet, the equilibrium $Fe_3O_4+H_2\rightleftharpoons3FeO+H_2O$ can be resolved into $2Fe_3O_4\rightleftharpoons6FeO+O_2$, and $2H_2O\rightleftharpoons2H_2+O_2$, while the equilibrium $Fe_3O_4+CO\rightleftharpoons3FeO+CO_2$ can be resolved into $2Fe_3O_4\rightleftharpoons6FeO+O_2$, and $2CO_2\rightleftharpoons2CO+O_2$. The pT-diagram for the case studied in connection with the action of hydrogen on ferric oxide ($q.v.$), shows that the 3-phase lines $FeO+Fe_3O_4+G$, and $Fe_2O_3+Fe_3O_4+G$ do not intersect in stability points, Fig. 23. Here the two 3-phase lines—two solid phases and vapour—intersect without inverse melting taking place. Fig. 24 represents the case where the two
FIGS. 23 and 24.—Pressure-temperature Equilibria for Carbon Monoxide and the Iron Oxides.

lines intersect in stable points. Here the 3-phase line Fe_3O_4+L+G is metastable. For the system : $Fe+CO_2\rightleftharpoons FeO+CO$, and $2CO_2\rightleftharpoons2CO+O_2$, $\log p_O = \log K_p - 2 \log K$, where p atm. refers to CO_2, and $K=p_{CO}/p_{CO_2}$. For the carbon· dioxide equilibrium, with the thermal value $-133,000$ cals. at 800°, $\log K_p = 29,100T^{-1} + \log T + 5·8$. Taking W. Reinders' values for $\log K_p$, the values of $\log K_p$, and $\log K_3$ at different temp., $\log P_{O_2} = \log K_p -2 \log K_3$; likewise for $\log K_2$ it follows that $\log P_{O_2} = \log K_p - 2 \log K_2$ for $3FeO+CO_2$ $\rightleftharpoons Fe_3O_4+CO$; and for $\log K'_3$ it follows that $\log P_{O_2} = \log K_p - 2 \log K_3$ for $3Fe+4CO_2$ $\rightleftharpoons Fe_3O_4+4CO$. The values are as follow :

	400°	500°	550°	600°	700°	800°	900°
log K_p . .	−34·6	−28·9	−26·7	−24·6	−21·1	−18·3 ·	−15·9
log K_1 . .	—	—	−0·01	−0·06	0·18	0·27	0·34
log P_{O_2} . .	—	—	−26·7	−24·7	−21·5	−18·8	−16·6
log K_2 . .	—	—	−0·11	−0·17	−0·29	−0·39	−0·49
log P_{O_2} . .	—·	—	−26·5	−24·3	−20·5	−17·5	−14·9
log K_3 . .	−0·16	−0·05	—	—	—	—	—
log P_{O_2} . .	−34·3	−28·8	—	—	—	—	—

The equilibrium conditions between iron and its oxides, and carbon monoxide and dioxide are not completely described by Fig. 25, because carbon may be formed : $2CO\rightleftharpoons C+CO_2$. It is therefore necessary to superpose on Fig. 25 the effects of this reaction on the results. W. A. Bone and co-workers studied the reduction of iron ores by carbon monoxide at temp. below 700°,·where the equilibria are metastable. The reactions involved are : $3Fe_2O_3+CO=2Fe_3O_4+CO_2$, which is exothermic and irreversible; and the reversible reactions : $Fe_3O_4+CO\rightleftharpoons3FeO$ $+CO_2\pm5·4$ Cals., and $FeO+CO\rightleftharpoons Fe+CO_2\pm2·6$ Cals. Free carbon was not deposited in appreciable quantities on the reduced ore until reduction had progressed so far that all the higher oxides had been reduced to Fe_3O_4 at 550° or a lower temp., or to FeO at 600° or a higher temp., and a small portion of either oxide had been reduced to iron, which then catalyzed the reaction $2CO\rightleftharpoons CO_2+C+39$ Cals. The higher the temp., the less the tendency for carbon deposition. The deposition of carbon at low temp. proceeds slowly at 275°, and its optimum temp. is 450°, but it does not occur in the absence of a suitable catalyzing surface. Iron, and ferrosic and ferrous oxides are powerful promoters of carbon deposition at temp. up to between 650° and 700°, but at higher temp. the phenomenon becomes inappreciable until nearly 90 per cent. of the ore is reduced, when it again becomes prominent. The carbon deposition in a blast-furnace may occur between 275° and 700°, and it may result in the impregnation of the ore with carbon, or the carbon may envelop the granules of ore, or both impregnation and envelop-

ment may occur. The impregnated carbon is a more powerful reducing agent at 750° than is the case with carbon monoxide. If carbide is formed, it is conditioned by the presence of free iron in a system containing both oxides of carbon and an ore undergoing reduction.

The data of O. Boudouard, at atm. press., are summarized by the curve DE, Fig. 25. The systems represented to the left of the shaded region refer to those in which no carbon is formed, whereas the shaded areas refer to systems in which, for equilibrium, some carbon is formed. Thus the system represented by the point a is not in stable equilibrium with respect to carbon, and that element will be deposited until the system acquires the state represented by b. The whole area for systems with the three components—Fe, C, and O—is thus divided by the equilibrium curves into six regions, namely A with iron; A' with iron and carbon; B with ferrous oxide; B' with ferrous oxide

FIG. 25.—Equilibria in the System with Iron, Iron Oxides, Carbon Monoxide and Dioxide, and Carbon.

and carbon; C with ferrosic oxide; and C' with ferrosic oxide and carbon. The point x involves the solid phases Fe, FeO, and carbon; and y, the solid phases Fe_3O_4, FeO, and carbon. R. Schenck and co-workers found the equilibrium press., p mm., of the gas in the system with the solid phases : iron, ferrous oxide, and carbon—(i) amorphous carbon from carbon monoxide, and (ii) from sugar charcoal, as well as (iii) graphite, were :

	(i)			(ii)			(iii)		
	455°	596°	670°	408°	560°	647°	500°	660°	755°
p	27	296	858	5·6	161·7	750·1	12·3	129	574

The results with Fe_3O_4, FeO, and amorphous carbon as solid phases are :

	528°	535°	551°	560°	568°	581°
p	121	129	175	303	430	699

They represent the results by the curves shown in Fig. 25. The ferrous oxide used in these experiments was prepared from ferrous oxalate, and it is possible that it was contaminated with carbon or carbide. A. Gautier and P. Clausmann observed that in the prolonged action of carbon monoxide on iron some carbon and carbide are formed: $3Fe +2CO=Fe_3O_4+16C+12CO_2$. H. C. H. Carpenter and C. C. Smith found that at 650° carbon monoxide reacts with iron, forming a carbide, and that the production of the carbide is inhibited if enough carbon dioxide be also present, and it is favoured by the presence of hydrogen. S. Hilpert and T. Dieckmann observed that when iron oxide is reduced by carbon monoxide, the product at 850° contained carbon; and between 720° and 800° the deposition of carbon was accelerated, presumably by the formation of unstable carbides. Free carbon was not observed until the product

FIG. 26.—Equilibrium in Systems with Iron, Iron Oxides and Carbide, Carbon, and Carbon Monoxide and Dioxide.

attained a composition eq. to Fe_3C with 6·6 per cent. of carbon. R. Schenck discussed the equilibrium $3Fe+2CO\rightleftharpoons Fe_3C+CO_2$; and also the reduction with methane involving $3Fe+CH_4\rightleftharpoons Fe_3C+2H_2$. The subject was studied by G. Tammann and A. Sworykin, F. Wüst, and W. Gluud and co-workers. V. Falcke found carbon is formed as a separate phase only when iron is treated for a long time in a current of carbon monoxide. This result is supposed to vitiate the results of R. Schenck indicated in Fig. 26. V. Falcke observed no reaction between carbon and ferrous oxide in an evacuated tube below 650°; and above this temp. different varieties of carbon acted at different speeds—amorphous carbon reacted with extreme slowness. V. Falcke also measured the equilibrium constants between carbon monoxide and different varieties of iron. If $K=[CO]^2/[CO_2]$ in the reaction $CO_2+C\rightleftharpoons 2CO$, when press. are expressed in atm.:

	$K_{600°}$	$K_{700°}$
Purified iron	0·230	1·57
Iron preheated in CO at 600°	0·146	1·27
Graphite and commercial FeO	0·115	1·18
Graphite and FeO from Fe	—	0·87
Calculated from free energies	0·080	0·965

The calculated values are due to E. D. Eastman. E. Terres and A. Pongracz inferred from the action of carbon dioxide on iron that carbon, and a solid soln. of ferrous and ferrosic oxides are formed. A. Matsubara studied the action of carbon monoxide on iron oxides, and found that the iron was carburized, forming an iron carbide as a separate phase; and his curves agree closely with those of W. A. Bone and co-workers for temp. of 750°, 850°, and 975°. A. Johansson and R. von Seth studied the equilibria in the reaction $3Fe+2CO\rightleftharpoons Fe_3C+CO_2$ between 700° and 1100°, and found that at about 700° the equilibria coincided with those of R. Schenck, but not at higher temp. R. Schenck supposed that the carbon press. of cementite is always greater than that of elementary carbon, but this is true only below 800°; above that temp. the carbon press. of cementite is lower. The
FIG. 27.—Equilibria in the System: $3Fe+2CO\rightleftharpoons Fe_3C+CO_2$ at different temperatures.
FIG. 28.—Equilibria in the Systems with Iron, Iron Oxides, Carbon, and Carbon Monoxide and Dioxide.

results are summarized in Figs. 27 and 28. The results in the first diagram refer to a press. of 40 per cent. of mixed carbon monoxide and dioxide and 60 per cent. of nitrogen; while the results in Fig. 28 have been calculated for a press. of the mixed carbon monoxide and dioxide equal to one atm. G. Chaudron noted that the curves $FeO-Fe_3O_4$ and $Fe-FeO$ meet at 570° to 580°. U. Hofmann and E. Groll showed that with carbon monoxide free from oxygen and iron prepared from the carbonyl, graphite and ferrosic oxide and a little carbide are formed below 450°; graphite and ferrous oxide and a little carbide and ferrosic oxide between 450° and 650°; graphite and carbide, but no ferrous or ferrosic oxide, above 655°. With purified ferric oxide and carbon monoxide, ferrosic oxide and carbide were formed at 275° and 320°; some unknown lines in the X-radiograms

were attributed to the carbide Fe_2C. The subject was discussed by R. Schenck and co-workers, W. Reinders, W. Reinders and P. van Groningen, K. Jellinek and A. Diethelm, K. Iwase and T. Watase, H. C. H. Carpenter and C. C. Smith, V. Falcke and co-workers, A. McCance, and K. Hofmann. M. L. Becker found that between 650° and 1000° graphite is stable with respect to iron carbide, for the vap. press. of the carbon vapour of iron carbide is higher than that of carbon alone, and the gas in equilibrium with iron carbide plus saturated solid soln. is richer in carbon monoxide than is the case with graphite at the same temp. A. Matsubara, and A. Johansson and R. von Seth considered the carbon vap. press. of the carbide to be lower, not higher, than that of graphite at temp. exceeding 800°—*vide infra,* the decarburization of cast iron.

H. Nippert found that the constant $K=[CO]^2/[CO_2]$ for the action of carbon monoxide on iron is higher for purified iron than for carburized iron ; and the
FIGS. 29 and 30.—Ternary System : Fe–C–O.

results with nickeliferous iron are lower than for carburized iron, and these results are taken to be the true equilibrium values, for the reaction is accelerated when nickel is present. R. Schenck, and J. Müller studied the effect of the presence of magnesia, and of silica on the equilibrium conditions ; R. Schenck and co-workers, the influence of alumina, manganese oxide, lime, beryllia, cobalt, and nickel ; and R. Schenck and co-workers, and P. van Groningen, the effect of other impurities.

K. Iwase and T. Watase attempted to represent the relations in the ternary system at 1130°–910° and 910°–726° by Figs. 29 and 30. Hence, B denotes FeO ; D, Fe_3O_4 ; E, CO_2 ; F, CO ; and H, Fe_3C ; while G_1, G_2, G_3, G_4, and G_5 represent mixtures of carbon monoxide and dioxide. The area $Ajhgi$ represents Fe ; f_2igh_1, Fe+FeO ; Hjh, Fe+Fe_3C ; HG_4G_3, Fe_3C ; G_1de, FeO +Fe_3O_4 ; G_2f_1g, FeO+Fe , G_3hH, Fe+Fe_3C ; $G_1ef_1G_2$, FeO ; G_2ghG_3, Fe ; and CkG_4, Fe_3C+C. E. Jänecke also represented results with the ternary system Fe–O–C by triangular diagrams. According to

FIG. 31.—Diagrammatic Representation of the Equilibrium Curves involving Fe, FeO, Fe_3O_4, C, CO_2, and CO, below 700°.

R. Schenck, the equilibrium conditions at a constant temp. below 700° can be represented diagrammatically by Fig. 31 ; the reactions : $2CO\rightleftharpoons CO_2+C$ (curve 5) ; FeO+CO$\rightleftharpoons$Fe+CO_2 (curve 3) ; $3FeO+5CO\rightleftharpoons Fe_3C+4CO_2$ (curve 2) ; $3Fe+2CO$

$\rightleftharpoons Fe_3C+CO_2$ (curve 1); and $Fe_3O_4+CO\rightleftharpoons 3FeO+CO_2$ (curve 4), are involved. The curves, Fig. 31, divide the area into 12 fields.

The reactions which take place in the different fields are : *Field A*—$3Fe+2CO=Fe_3C$ $+CO_2$; $3FeO+5CO=Fe_3C+4CO_2$; $FeO+CO=Fe+CO_2$; $Fe_3O_4+CO=3FeO+CO_2$; and $2CO=C+CO_2$. *Field* B_1—$Fe_3C+CO_2=3Fe+2CO$; $3FeO+5CO=Fe_3C+4CO_2$; $FeO+CO=Fe+CO_2$; $Fe_3O_4+CO=3FeO+CO_2$; and $2CO=C+CO_2$. *Field* B_2—the first four reactions of B_1 apply here, and in addition $C+CO_2=2CO$. *Field* C_1—Fe_3C+CO_2 $=3Fe+2CO$; $Fe_3C+4CO_2=3FeO+5CO$; $FeO+CO=Fe+CO_2$; $Fe_3O_4+CO=3FeO$ $+CO_2$; and $2CO=C+CO_2$. *Field* C_2—the first four reactions for the field C_1 apply here, and in addition $C+CO_2=2CO$. *Field* D_1—$Fe_3C+CO_2=3Fe+2CO$; $Fe_3C+4CO_2=3FeO$ $+5CO$; $Fe+CO_2=FeO+CO$; $Fe_3O_4+CO=3FeO+CO_2$; and $2CO=C+CO_2$. *Field* D_2— the first four reactions for the field D_1 apply here, and in addition $C+CO_2=2CO$. *Field* E_1—$Fe_3C+CO_2=3Fe+2CO$; $Fe_3C+4CO_2=3FeO+5CO$; $Fe+CO_2=FeO+CO$; $3FeO$ $+CO_2=Fe_3O_4+CO$; and $2CO=CO_2+C$. *Field* E_2—the first four reactions for the field E_1 apply here, and in addition $C+CO_2=2CO$. *Field F*—$3Fe+2CO=Fe_3C+CO_2$; $3FeO$ $+5CO=Fe_3C+4CO_2$; $Fe+CO_2=FeO+CO$; $Fe_3O_4+CO=3FeO+CO_2$; and $2CO$ $=C+CO_2$. *Field G*—$3FeO+5CO=Fe_3C+4CO_2$; $Fe_3C+4CO_2=3FeO+5CO$; $Fe+CO_2$ $=FeO+CO$; $Fe_3O_4+CO=3FeO+CO_2$; and $2CO=C+CO_2$. *Field H*—$3Fe+2CO$ $=Fe_3C+CO_2$; $Fe_3C+4CO_2=3FeO+5CO$; $Fe+CO_2=FeO+CO$; $3FeO+CO_2=Fe_3O_4$ $+CO$; and $2CO=C+CO_2$—*vide infra*, ferrous oxide.

The end-products are cementite and carbon in the fields A and F; metallic iron and carbon in fields B_1 and C_1, without the simultaneous precipitation of carbon in fields B_2 and C_2; ferrous oxide with carbon in the fields D_1 and G; ferrous oxide without carbon in the field D_2; ferrosic oxide with carbon in the field E_1 and H; and ferrosic oxide without carbon in the field E_2. Consequently, at any given temp., any of the four solids can be obtained as a stable phase by simple variations of the composition and press. of the gas phase. If the temp. be raised, all the fields are modified, the curvatures of the boundary lines alter, and the curves are displaced to the right. If, then, a third dimension, temp., be included in the diagram, the resulting figure would be a geometrical representation of the whole theory of the blast-furnace. The subject is discussed from other points of view in connection with ferrous oxide and also ferric oxide.

R. Schenck continued : Unlike the other solid phases, cementite is stable only in fields where carbon monoxide is labile and subject to decomposition into carbon and carbon dioxide. Consequently, cementite is not formed from carbon and the metal, and the only cementing agent which can form the tritacarbide directly is carbon monoxide. Cementite, however, can be formed by the action of carbon on ferrous oxide in field B. Solid carbon can act as a cementing agent if it is not in the formation of cementite as a separate phase, but in the formation of a solid soln. of this substance with metallic iron. If the temp. for the formation of the solid soln. falls inside the field C_2, the field in which at temp. below 770° metallic iron is the only stable solid phase, the reaction $Fe_3C+CO_2\rightleftharpoons 3Fe+2CO$ becomes reversible. The composition of the solid soln. is dependent on the press. and composition of the gas, and this is also the case for the reaction $FeO+CO\rightleftharpoons Fe$ (containing $Fe_3C)+CO_2$. H. Tutsya observed that in the ferric oxide and carbon monoxide reaction X-radiograms show that the reduction proceeds $Fe_2O_3\rightarrow Fe_3O_4$ $\rightarrow FeO\rightarrow Fe_3C$. The deposition of carbon was also studied by W. A. Bone and co-workers, A. Ledebur, and M. L. Becker.

The equilibrium conditions between the oxides of iron and of carbon have been fairly well established by the work of R. Schenck, but the mechanism of the reaction between the oxides of carbon and iron resulting in the formation of the iron carbides and carbon is not so clear. It is doubtful if the reaction $2CO\rightleftharpoons C+CO_2$ progresses directly at temp. below 680°; it is more likely that the free carbon is indirectly formed as a consequence of the decomposition of an iron carbide. As just indicated, R. Schenck assumed that cementite, *i.e.* iron tritacarbide, is the solid phase. According to U. Hofmann, although cementite is always present when a separation of carbon has taken place, yet it is improbable that the carbon is produced by the decomposition of the cementite, because if that compound be heated for 2 hrs. below 450° in nitrogen no decomposition can be detected, but if the cementite

be formed from carbon monoxide under similar conditions, ten times as much carbon is produced as could be obtained by the decomposition of the cementite. H. Tutsya assumed that the carbon is here formed by the reaction $2CO=C+CO_2$, catalyzed by the cementite, but (i) U. Hofmann showed that the properties of the resulting carbon make this improbable ; (ii) R. Schenck could not determine the state of equilibrium of the reaction below $680°$; and (iii) the equilibrium proportions of carbon dioxide measured by U. Hofmann and E. Groll are always less than those required on the assumption that the carbon is produced by the reaction $2CO=C+CO_2$.

W. Gludd and co-workers, and F. Fischer and H. Bahr observed that at low temp., between $275°$ and $320°$, the separation of carbon proceeds very slowly, and the X-radiogram shows that the space-lattice of what is thought to be iron hemi-carbide, Fe_2C, appears, provided the temp. is below $400°$. It is therefore assumed that the hemicarbide decomposes rapidly in the vicinity of $400°$. S. Hilpert first assumed the existence of higher carbides than the tritacarbide. The X-ray spectral lines of the hemicarbide agree with those observed by R. Brill and H. Mark for $FeCy_2$; and with those observed by A. Mittasch and E. Kuss for an unknown carbide. U. Hofmann and E. Groll also observed the presence of the space-lattice of the assumed hemicarbide associated with that of ferrosic oxide in the decomposition products of ferric oxide by carbon monoxide between $275°$ and $320°$. H. Tutsya did not detect the presence of this carbide, but he is thought to have worked at too high a temp., for U. Hofmann and E. Groll observed that the decomposition per hour, using 0·2 grm. of iron and a rapid current of carbon monoxide, results in the separation of :

	250°	320°	420°	450°	500°
Carbon	0·5	1·6	26·0	55·0	77·0 mgrms.

These data are considered to represent the speed of decomposition of the hemi-carbide, and they are also taken to correspond with the rate at which carbon is produced in the action of carbon monoxide on iron below $400°$. No evidence of the formation of the hemicarbide was observed in the action of a slow current of carbon monoxide on iron at $510°$—only ferrosic oxide, carbon, iron, and cementite were formed ; but at $585°$ only iron, carbon, and cementite were present ; no ferrosic oxide could be detected. With a rapid current of carbon monoxide, at $450°$ to $700°$, the quantity of carbon dioxide formed is below that required for equilibrium, and only iron and cementite were present in the solid phase. No decomposition of cementite was observed at $450°$ for 2 hrs. in an atm. of nitrogen ; but when kept at the temp. of its formation for 2 hrs. the cementite was completely decomposed into carbon and iron. The general conclusion of U. Hofmann and E. Groll is that at these low temp. the carbon produced by the action of carbon monoxide on iron or on ferrosic oxide is a result of the formation and subsequent decomposition of iron hemicarbide.

E. Baur and A. Glässner calculated for the thermal value of the reaction $Fe+CO_2 \rightleftharpoons FeO+CO$, -8724 cals. at $835°$; hence the formation of carbon monoxide is favoured by a rise of temp. They found for the reaction $Fe_3O_4+CO \rightleftharpoons 3FeO+CO_2$, -5176 cals. at $765°$, and $+6563$ cals. at $400°$. G. Bodländer gave for the free energy of the reduction of ferrous oxide by carbon : $-34,950+35\cdot26T-4\cdot58$ log p_{CO}. S. Hilpert said that this reaction begins at $240°$ and that the product of the reaction is carbonaceous. For the reaction $Fe+CO_2=FeO+CO$, G. Chaudron calculated the heat of formation to be $-3\cdot4$ Cals. per mol at $17°$, and $-2\cdot0$ Cals. at $650°$; and K. M. Tigerschiöld gave $-1\cdot8$ Cals. at $17°$. G. Chaudron gave for the reaction $3FeO+CO_2=Fe_3O_4+CO$, $9\cdot0$ Cals. per mol at $17°$, and $6\cdot8$ Cals. at $650°$; whilst K. M. Tigerschiöld gave $4\cdot0$ Cals. at $17°$. G. Chaudron gave for the reaction $3Fe+4CO_2=Fe_3O_4+4CO$, $-1\cdot2$ Cals. per mol at $17°$, and $-2\cdot0$ Cals. at $650°$, whilst K. M. Tigerschiöld gave $1\cdot4$ Cals. at $17°$. K. M. Tigerschiöld gave $>16\cdot25$ to $<18\cdot8$ Cals. per mol. for the thermal value of the reaction $3Fe_2O_3+CO$ $=2Fe_3O_4+CO_2$ at $17°$. The thermal values of these reactions were also discussed

by H. le Chatelier, P. van Groningen, and E. D. Eastman. H. L. Maxwell and A. Hayes gave $3a\text{-}Fe+C_{graphite}=Fe_3C_{solid}+19\cdot163$ Cals. at 650° ; and 19·161 Cals. at 700°. U. Hofmann and E. Groll calculated for the reaction $3Fe+4CO_2=Fe_3O_4+4CO$, —5380 cals. ; and for $Fe_3O_4+6CO=Fe_3C+5CO_2$, —41,850 cals.

The simultaneous action of hydrogen and carbon monoxide in the quaternary system Fe–O–C–H was discussed by G. Chaudron, E. D. Eastman and R. M. Evans, K. Hofmann, and R. Schenck. The results of these observations have been applied by W. Reinders, T. H. Byrom, L. Guillet, F. H. Willcox, D. Sillars, E. Bertram, G. Bulle, A. Michel, B. Osann, C. Zix, H. Bansen, M. Levin, F. Wüst, I. Bohm, S. P. Kinney, H. H. Meyer, W. van Vloten, G. S. J. Perrott and S. P. Kinney, H. A. Brassert, W. Lennings, K. Hofmann, A. Wagner, F. Kupelweiser and R. Schöffel, H. Kinder, J. E. Johnson, W. Mathesius, F. Clements, F. A. Kjellin, E. G. Odelstjerna, G. W. Vreeland, A. K. Reese, W. G. Imhoff and co-workers, F. T. Sisco, E. Diepschlag and K. Feist, A. L. Boegehold, J. E. Fletcher, R. Schenck and co-workers, K. Iwase and T. Watase, H. Mehner, W. A. Bone and co-workers, N. Metz, H. Kamura, L. E. Gruner, H. J. van Royen, etc., to bring out the nature of the reactions involved in the reduction of iron ores in the blast-furnace. The relative ease of the reducibility of iron ores was discussed by H. Tholander,[5] B. Bogitch, E. A. Uehling, O. Simmersbach, B. Stålhane and T. Malmberg, J. Klärding, H. Seigel, S. Sugimoto, G. Yamada, M. Kawaguchi, R. H. Sweetser and S. P. Kinney, R. Baake, A. Weiskopf, A. D. Elbers, and J. Wiborgh. The greater the density, the less readily is the ore reduced ; ores which are porous after they have lost their volatile matter are readily reduced. C. H. Desch emphasized that the formation of a film of impervious carbon on ore may hinder the reduction. H. Braune discussed the work done by nitrogen reactions in the blast-furnace, and added that cyanogen is the substance from which iron most readily takes up carbon in the blast-furnace—*vide supra.*

The disintegration of firebricks is associated with the action of carbon monoxide about the ferric oxide, etc., present as " iron spots " in the materials, resulting in the deposition of carbon in the interior of the firebricks. This may be attended by a bursting or shattering of the firebricks. The subject was discussed by E. Diepschlag and K. Feist,[6] A. T. Green and co-workers, R. P. Heuer, H. K. Mitra and A. Silverman, C. E. Nesbitt and M. L. Bell, B. M. O'Harra and W. J. Darby, B. Osann, S. M. Phelps, and P. Rischbieth.

§ 5. The Manufacture of Wrought Iron

Wrought iron is iron which has been produced in a pasty condition below its m.p. ; it contains a relatively low proportion of carbon and other impurities. It is associated with a small proportion of slag, which is originally present in the metal as granules, or separate particles, but when rolled into strips or bars the granules are elongated so as to impart a fibrous structure to the metal. Wrought iron melts at about 1500°, it can be welded, and is ductile when cold. It is not appreciably

hardened when quenched from a red-heat in water. It thus differs from both steel and cast iron—*vide infra*, nomenclature. In the old methods for extracting iron from its ores, wrought iron was nearly always the direct product—*vide supra*, the extraction of iron. The open-hearth processes of the Romans in Britain, the primitive processes used by the natives of India and Africa, and the old Catalan forge process, as well as the American bloomery process, all yield a mass or bloom of what might be called spongy wrought iron. Charcoal fuel is employed. If coke were used, the metal in that state has a great avidity for any sulphur present, and the finished metal becomes red-short. The iron produced in the old osmund furnaces, the small blast-furnaces of India (H. Harris,[1] A. R. Roy, C. von Schwarz, and E. Stöhr), China (T. T. Read, and A. B. Middleton), Madagascar (G. P. Chaplin), Persia (J. Robertson), and West Africa (C. V. Bellamy, G. A. Schweinfurth, T. T. Read, and C. V. Bellamy), as well as in some of the taller *Stückofens* of Europe, yielded wrought iron. The blooms produced in the early process with a stationary hearth were described by C. Husgafvel, G. Agricola, V. Biringuccio, L. Beck, B. Osann, T. A. Rickard, E. Swedenborg, L. Beck, etc.

A. Chenot obtained wrought iron without smelting the ore by the direct reduction of hæmatite mixed with about one-fifth its weight of charcoal by heating it in retorts. The process was discussed by P. R. von Tunner, M. Baills, A. Gurlt, E. Grateau, and J. Percy, but it could not compete against the cheaper process of smelting for cast iron, and subsequently converting the cast iron into wrought iron. Other proposals of a similar nature, but more or less modified, were made by C. Adams, W. Arthur, O. Daube, M. Baills, A. E. Bellford, W. F. Berner, T. S. Blair, Bulls Iron and Steel Co., Ltd., W. N. Clay, C. Otto, R. M. Daelen, A. Dickenson, E. F. Fleischer, G. Günther, J. I. Hawkins, H. Leobner, W. Henderson, W. Ivanoff, J. H. Johnson, H. A. Jones, P. Justice, J. Leinberger, S. Lucas, W. Mills, W. Moore, D. Mushet, W. E. Newton, C. Otto, F. Projahn, C. S. Quillard, J. Renton, I. Rogers, A. Sattmann and A. Homatsch, E. Servais and P. Gredt, C. W. von Siemens, F. von Siemens, O. Simmersbach, O. Thieblemont, O. Thiel, F. Uchatius, G. A. Whipple, F. Yates, etc., where the heating was done in reverberatory rotary furnaces. These also came to nothing. Modifications devised by T. S. Blair, C. Adams, and H. H. Eames have been worked at Pittsburg, and they have been described by J. A. Hunt, J. Ireland, J. von Ehrenwerth, A. Ledebur, A. L. Holley, and H. von Jüptner.

The production of the so-called *spongy iron*—*vide infra*—has been discussed by E. P. Barrett,[2] P. M. Bonnerup, E. Edwin, B. Kalling and G. Lilljequest, B. Stoughton, N. K. G. Tholand, G. B. Waterhouse, M. Wiberg, P. E. Williams and co-workers, etc. ; and there are numerous proposals described in the records of the Patent Offices. Here the iron is formed at a temp. below its m.p. The so-called *synthetic iron* or *direct process iron* has been discussed by E. P. Barrett,[3] L. P. Basset, W. Baukloh and R. Durrer, A. E. Bourcoud, E. Bremer. E. W. Davis, K. Dornhecker, J. von Ehrenwerth, P. H. Emmett, H. Fleissner and F. Duftschmid, H. Flodin, E. Fornander, A. Gandini, A. Gurlt, H. Groebler and P. Oberhoffer, A. Groenwalt, G. Gröndal, E. G. T. Gustafsson, H. Harris, F. Hodson and O. Smalley, G. Hooghwinkel, R. E. Hore, E. Houbaer, C. Husgafvel, K. Iwase and M. Fukusima, K. Iwase, M. Fukusima and S. Mitsukuri, K. Iwase and Y. Saito, H. Kamura, K. Klöpper, J. D. Knox, H. Lang, J. A. Leffler, H. Leobner, T. Levoz, V. Lindt, C. Longenecker, P. Longmuir, S. L. Madorsky, H. H. Meyer, O. Meyer and W. Eilender, J. W. Moffat, R. H. Monk and R. J. Traill, I. Moscicki, C. E. Parsons, D. Perietzeanu, C. P. Perin, J. W. Ramsay, T. T. Read, S. E. Sieurin, J. K. Smith, H. Stamm, B. Stålhane, W. F. Sutherland, R. J. Traill and W. R. McClelland, G. B. Waterhouse, R. Whitfield, J. G. Wiborgh, L. Wickenden, C. E. Williams, E. P. Barrett and B. M. Larsen, F. Wüst, etc. There are numerous patents described in the records of the Patent Office.

The exact date is unknown when, in the Middle Ages, tall blast-furnaces were regularly used, for the production of cast iron, and the cast iron was subsequently

purified in special furnaces so as to convert it into malleable wrought iron. At first one refining hearth was employed, and where the metal was required of still greater purity a second was used. The manufacture of iron wire by drawing was described by Theophilus,[4] who wrote in the eleventh century. In 1676, H. Powle thus described the conversion of cast or pig iron into malleable or wrought iron as practised in the ironworks of the Forest of Dean :

> From these furnaces (high blast-furnaces) they bring their sows and pigs of iron to their forges. These are of two sorts, though standing together under the same roof : one they call their Finery, the other the Chafery. Both of them are open hearths, on which they place great heaps of sea-coal, and behind them bellows, like those of the furnaces, but nothing near so large. Into the Finery they first put their pigs of iron, placing three or four of them together behind the fire, with a little of one end thrust into it. Where, soften-ing by degrees, they stir and work them with long bars of iron, till the metal runs together into a round mass or lump, which they call a half-bloom. This they take out, and giving it a few strokes with their sledges, they carry it to a great weighty hammer, raised likewise by the motion of a water-wheel, where applying it dexterously to the blows, they presently beat it out into a thick, short square. This they put into the Finery again, and heating it red hot, they work it out under the same hammer, till it comes into the shape of a bar in the middle with two square knobs in the ends. Last of all, they give it other heatings in the Chafery, and more workings under the hammer, till they have brought their iron into bars of several shapes and sizes, in which fashion they expose them to sale.

The refining hearths were at first very simple, but they gradually became more and more complex, owing to modifications being introduced to suit local con-ditions. The open hearth refinery was called in Germany the *Frischofen* or *Frischherden*. There are some in use in Styria and a few other localities. They have been described by P. R. von Tunner, J. W. Hall, A. Wigand, J. Percy, F. Maresch, G. Jars, E. Thirria, E. Audibert, S. Homfray, F. Botischeff, F. Over-mann, M. Stengel, M. Wachler, R. Akerman, and J. von Ehrenwerth. The pig-iron is melted on the hearth, which contains charcoal and the so-called hammer slag or iron scale—mainly ferrosic oxide, Fe_3O_4. Air is also blown in at the same time, and the iron is freely sprinkled with slag. The iron is decarburized by the joint action of the air blast and the oxidizing slag. It is possible to obtain wrought iron or steel by suitable modifications of the process.

In 1784, H. Cort [5] patented a process in which the decarburization and purifi-cation were conducted in a reverberatory furnace with a hollow bottom, so as to contain the metal in a fluid state. Patents closely related to that of H. Cort were obtained by T. and G. Cranage, in 1766, and by P. Onions, in 1783. At first white pig-iron was treated in furnaces with a siliceous bottom. This lining was rapidly attacked, and renewals were costly. The process was called *dry puddling*. The process was also wasteful of iron, for only 70 per cent. yields were in some cases obtained. The dry puddling process was described by T. Beddoes, J. Percy, V. Couailhac, C. Hartmann, J. M. Bineau, L. Ansiaux and L. Masion, St. J. V. Day, C. W. von Siemens, A. A. Fesquet, C. Otto, H. Scrivenor, T. Turner, etc. S. B. Rogers is said to have introduced the " iron bottom " about 1818 ; and there are references to the subject in the patents of R. Gardner, in 1642, and W. Taylor, in 1793. The introduction of old bottom-material, consisting mainly of iron silicate and ferrosic oxide, produced more slag, and hence it was called *wet puddling*, but the yields were greater—amounting in some cases to 90 per cent. J. Hall is generally credited with the introduction of the modern *pig-boiling process* into works practice. The name is applied to wet puddling in allusion to the vigorous bubbling or " boiling " of the molten metal owing to the formation of carbon monoxide by the oxidation of the carbon in the iron by the oxides in the furnace bottom. The gas burns with a blue flame at the surface of the metal. The jets of flame are called *puddlers' candles*, also called sulphur, in allusion to the colour of the flame.

The puddling process has been discussed by L. Beck, R. Biedermann, G. A. C. Bremme, J. G. Danks, C. H. Desch, M. Düber, H. Fehland, F. Sauvage, R. Smith, C. D. af Uhr, and A. Gounot. The operation of puddling has been

described in detail by J. Percy, T. Turner, etc. The diagrams, Figs. 32 and 33, of a puddling-furnace were given by J. Percy. The pig-iron is placed on the bed of the furnace, and melted down by the heat from the firemouth, F. The operation requires about half an hour, and during this operation most of the silicon and manganese, as well as a large proportion of phosphorus, is eliminated. The molten metal is allowed to "clear" for about 10 minutes, during which nearly all the silicon and manganese are eliminated and more phosphorus is removed. During the clearing the metal is well stirred by means of a bar bent at right angles inserted in the aperture d, Fig. 32. The whole charge thus is exposed to the action of the fettling and cinder, and to some extent to the oxidizing action of the air. The furnace-draught is then diminished, and a smoky flame is produced. The metal is also vigorously stirred so that it comes in contact with the cinder. This is the so-called boiling stage. The violence of the reaction gradually diminishes, and in about half an hour the *balling-up stage* begins. Here the puddler works the iron into cakes of metal of a convenient size for subsequent treatment. The balling occupies about 20 minutes. The balls, approximately 80 lbs. in weight, are withdrawn from the furnace and hammered to remove much of the slag. The bloom of iron which results is then rolled to form *puddled bars* of wrought iron. J. Hall thus summarized the process of puddling :

FIG. 32.—Outside Elevation of Puddling-Furnace.

First, charge the furnace with good forge pig-iron, adding, if required, a sufficiency of flux—increasing or diminishing the same in proportion to the quality and nature of the pig-iron used. Secondly, melt the iron to a boiling or liquid constituency. Thirdly, clear the iron thoroughly before dropping down the damper. Fourthly, keep a plentiful supply of fire on the grate. Fifthly, regulate the draught of the furnace by the damper. Sixthly, work the iron into one mass before it is divided into balls ; when thus in balls, take the whole to the hammer as quickly as possible, after which roll the same into bars for mill purposes.

The different oxidizing agents, or *fettling*, employed in the puddling-furnace consist of the so-called *hammer-slag* or cinder obtained from the compression of the puddle-balls. It is a ferrous silicate containing ferrosic oxide. The object of the
FIG. 33.—Section through Puddling-Furnace.

"flux" is to provide a bath of liquid cinder into which the globules of cast iron may trickle as the metal melts. The sides of the cavity of the furnace bottom consist of *bull-dog*, obtained by calcining tap-cinder. Bull-dog is a ferrous silicate containing more ferrosic oxide than hammer slag. The so-called *blue billy* or *purple ore* is also used ; it is a by-product obtained in the oxidation of iron pyrites

in the manufacture of sulphuric acid. Compact lumps of ferrosic oxide are used for making the sides of the basin in which the metal is melted. This material may be the tap-cinder obtained by working a mill furnace with an oxide bottom, or it may be obtained by calcining a suitable iron ore. The puddler prepares the bed and introduces about $4\frac{1}{2}$ cwts. of pig-iron for another run. The *tap-cinder* or ferrous silicate slag produced in the puddling-furnace includes the "boilings" which splashes over the fore-plate during the heating, and the "tappings" which is removed at the end of the process. The former alone contains "shots" of metallic iron. T. Turner gave :

	Fe_2O_3	FeO	SiO_2	P_2O_5
Boilings . . .	6·94	62·61	19·45	6·32 per cent.
Tappings . .	12·90	64·62	15·47	3·91 per cent.

T. Turner thus described the process of what might be called the differential oxidation of the impurities in cast iron :

If a globule of cast iron be melted in the air, and then exposed to a blast of air or oxygen, it will be observed that the impurities are not the only substances that are oxidized. It is true that, under very special conditions, either the carbon or the silicon may be separately oxidized. But on performing the experiment above indicated it will be found that the iron itself is oxidized in about the same relative proportion as the other elements, and the result is that practically a layer of impure magnetic oxide of iron is formed outside the globule, while the portion of metal that is left is of nearly the same composition as the original iron. If the cinder be allowed to run away as rapidly as it is formed, ultimately the whole of the iron would be converted into magnetic oxide, and the last particle of cast iron so removed would have nearly the same composition as the original metal. In this case oxidation has taken place, but no purification has resulted. If, now, the same experiment be tried, but the fluid oxide be allowed to remain and to cover the fused metal, the oxidation of the iron will proceed very little further ; a reducing action will then be commenced whereby the silicon, carbon, and other easily oxidizable elements will be removed, but at the same time a corresponding weight of iron will be returned to the globule from the surrounding slag. But if, thirdly, a globule of cast iron be covered with magnetic oxide of iron to protect it from the air and to supply the necessary cinder, and it be then strongly heated, it will be found that the globule has not lost in weight, but has become distinctly heavier during the process. It is scarcely necessary to say that the waste which takes place during reheating or remelting corresponds to the first condition above given. The oxide runs away as it is formed, and this is an example of waste of iron pure and simple. The only redeeming feature is that sometimes the oxide produced may be of value for other purposes. The early open-hearth processes for producing wrought iron in fineries, and the original method of puddling, resemble the second case, for part of the iron is wasted to produce the cinder needed to remove the impurities from the remainder of the metal. The larger the proportion of these impurities, the greater will be the loss of iron necessary to make the required cinder, and for this reason a comparatively pure iron is needed, in order to obtain the least waste, while at best the waste is comparatively great. A deficiency of fluid cinder in the early stages of ordinary puddling or "pig boiling" has an exactly similar effect, and leads to waste for the same reasons. In the modern method of working, on the other hand, the object is to imitate the conditions of the third case previously supposed.

I. L. Bell represented the effect of puddling on the composition of cold-blast pig-iron by the following analyses :

	Carbon	Silicon	Sulphur	Phosphorus
Pig-iron . . .	3·656	1·255	0·033	0·565 per cent.
Finished iron .	0·226	0·109	0·012	0·064 per cent.

H. von Jüptner gave for the composition of blooms made from charcoal and coke pig-irons, and of the wrought irons produced from them :

			C	Si	Mn	S	P	Cu	Fe
Bloom	Charcoal	(i)	0·207	0·108	0·644	0·005	0·033	tr.	98·892 per cent.
		(ii)	0·287	0·132	0·587	0·005	0·037	tr.	99·822 per cent.
	Coke	(iii)	0·116	0·169	0·628	0·006	0·068	0·003	99·870 per cent.
		(iv)	0·281	0·207	0·706	0·018	0·121	0·004	98·391 per cent.
Wrought iron	Charcoal	(i)	0·121	0·074	0·573	0·004	0·021	tr.	99·103 per cent.
		(ii)	0·127	0·094	0·538	0·006	0·027	tr.	99·154 per cent. .
	Coke	(iii)	0·101	0·069	0·581	0·005	0·048	0·003	98·586 per cent.
		(iv)	0·120	0·133	0·658	0·012	0·104	0·003	98·586 per cent.

The slags contained in the blooms and wrought irons had the compositions :

		Slag in Blooms			Slag in Wrought Iron		
		SiO_2	Fe_2O_3	MnO	SiO_2	Fe_2O_3	MnO
Charcoal	(i)	0·018	0·189	0·011	0·040	0·156	0·009
	(ii)	0·018	0·189	0·005	0·042	0·188	0·004
Coke	(iii)	0·012	0·101	0·009	0·054	0·095	0·005
	(iv)	0·018	0·242	0·012	0·048	0·319	0·017

Some of the properties and the manufacture of wrought iron were described by W. Richards, J. Aston, J. Kitson, E. Matheson, and F. L. Garrison. D. S. Price and E. C. Nicholson noticed how quickly the silicon is eliminated during the oxidation of pig-iron, even before a sensible amount of carbon has been removed. The theory of the process was also discussed by J. Percy. The changes in composition at different stages of the puddling were described by F. C. Calvert and R. Johnson, C. Lan, and L. Cubillo. The observations of A. E. Tucker on the relative rates of the differential oxidation of the chief impurities in cast iron are summarized in Fig. 34. H. Bauerman also said that the impurities are removed in the order : silicon, manganese, phosphorus, and lastly sulphur. The oxidation of the impurities is due in part to the oxygen of the air, and in part, as emphasized by G. J. Snelus, to the ferric oxide, but, as shown by L. Cubillo, the main oxidation is due to the ferrosic oxide in the fettling. Indeed, C. W. von Siemens said that the removal of the silicon and carbon from pig-iron in the ordinary pig-boiling process is entirely due to the molten iron oxide, and that an equivalent amount of iron is at the same time produced and

FIG. 34.—Progress of Refining during the Puddling of Cast Iron.

added to the bath. The gain of iron is, however, lost in subsequent stages of the process. Each unit of silicon in the pig-iron which is oxidized by ferrosic oxide introduced 2·8 times its weight of iron, or three parts of iron is produced for each unit of silicon oxidized to silica. T. Turner favoured the same hypothesis. L. E. Gruner suggested that ferrous oxide acts as a carrier of oxygen from the atmosphere to the impurities in the cast iron.

J. Percy assumed that the phosphorus is present in the iron as iron phosphide, and since when molten pig-iron is cooled the portions which solidify last are richest in phosphorus, there is a tendency for the phosphide in the balled iron in the bath of cinder to separate by liquation or sweating. The observations of G. J. Snelus, J. E. Stead, and T. Turner have shown that the elimination of phosphorus is due to its oxidation to phosphate by the iron oxide, partly during the melting stage and partly during the quiescent stage which precedes the boil. Once the metal has become granular, the elimination of phosphorus almost entirely ceases. The presence of silicon and of an excess of manganese retards the elimination of phosphorus. Sulphur is present in the iron and also in the slag as iron sulphide, and virtually no sulphur is eliminated as sulphur dioxide ; consequently, it appears as if the iron sulphide is shared between the iron and slag in accord with the partition law. J. E. Stead observed that in slags, iron sulphide and oxide exist side by side without interaction. The chemistry of the subject has been discussed by H. Louis, F. A. Matthewman and A. Campion, P. M. Macnair, A. Jung, F. T. Sisco, J. Kollmann, K. List, A. Schilling, M. Drassdo, and F. Gouvy.

Various substances have been proposed as additions during the puddling process to hasten the elimination of impurities. A. Guenyveau, and J. Nasmyth proposed introducing steam as well as atm. air into the puddling-furnace, and, according to J. Percy, G. Parry obtained some success in the desulphurization and dephosphorization of pig-iron by this process. It was assumed that sulphur escapes
as hydrogen sulphide and the phosphorus as phosphine, but this has not been proved. J. Payne suggested the use of " the ashes of wood and other vegetables, all kinds of glass and sandever (*i.e.* glass gall), common salt and rock salt, argile, kelp, and pot ash, and slagg or cinders from iron furnaces and forges " ; J. Wood, " lime, kelp, and soaper's waste " ; J. Goodyer, " common salt and other saline substances " ; D. Mushet, and S. B. Rogers, " unslaked lime, salt, nitre, and manganese oxide " ; and R. Richter, and G. Faller, litharge. J. Gibbons also recommended limestone, but J. Percy added that it is liable to make the iron red-short and rotten. Good results, however, were obtained by A. E. Tucker, and H. A. Webb. J. D. M. Stirling patented the use of tin for increasing the hardness of the finished metal ; and G. Allan described the effect of aluminium. Few of these or other additions have been successful, and none is regularly employed to any great extent.

In J. Aston's modification the pig-iron is melted in a cupola, the molten metal is refined in a bessemer converter, and a slag of the proper composition is prepared in an open-hearth furnace. The mechanical disintegration of the iron, and the incorporation of it with the slag are attained by pouring a charge of the molten refined iron into a bath of the molten slag. The squeezing of the ball of iron into a convenient form for working involves no new principle, nor does the mechanical working of the squeezed iron into a form suitable for handling in subsequent operations. The process and product were examined by H. S. Rawdon and co-workers. There is very little difference in the composition, structure, density, mechanical properties, and resistance to corrosion between wrought iron prepared by hard-puddling and that obtained by J. Aston's process. The subject was discussed by W. von Gutmann and H. Esser, and A. Mitinsky.

Improvements in the puddling-furnace, principally in the direction of gas-firing, have been proposed by J. Head, O. Springer, J. A. Detmold, P. Onions, H. de Simencourt and S. H. Blackwell, A. Raze, B. Kosmann, E. Laudron, E. Goedicke, F. Siemens, G. Pietzka, and H. Wedding ; A. le Play described the Carinthian process of puddling with wood as fuel. Other processes of making wrought iron have also been proposed by J. Aston, D. E. Roberts, E. Bonehill, A. M. Byers, A. H. Beale and co-workers, etc. F. L. Garrison, O. Murisier, etc., described furnaces with movable hearths. Methods of mechanical puddling have been discussed by W. H. Tooth, J. S. Jeans, J. P. Roe, S. Danks, J. Head, P. F. Nursey, W. Yates, J. I. Williams, F. H. Dechant, H. D. Hibbard, S. Jordan, R. Howson, H. Kirk, G. Hofer, E. F. Smith, J. T. Jones, J. A. Jones, P. Roberts, J. Lester, A. Spencer, G. J. Snelus, J. J. Bodmer, F. A. Paget, T. Gidlow, etc. This appears to be largely an engineering problem. Attempts to obtain iron directly from the ore in reverberatory furnaces were discussed by E. W. Davis, E. Laudron, H. Leobner, C. Otto, and C. R. von Schwarz.

§ 6. The Manufacture of Steel

Steel is the mainspring of modern industry. The commercial importance of steel is greater than that of gold, silver, zinc, copper, and lead combined, and, indeed, the trite saying that this is an age of iron is well-founded.—W. M. JOHNSON.

As a first approximation, **steel** can be regarded as an iron-carbon alloy intermediate in composition between wrought and cast iron—*vide infra*, nomenclature. The preparation of wrought iron has been considered from two aspects : (i) the

direct reduction of the metal from its ore in the form of blooms which are consolidated by forging, and (ii) the formation of cast iron, which is subsequently decarburized. The preparation of steel can be considered from four aspects : (i) the direct production of iron associated with carbon from iron ores ; (ii) the carburization of wrought iron ; (iii) the fusion of a mixture of wrought and cast iron ; and (iv) the partial decarburization of cast iron.

About 30 B.C., Diodorus Siculus, in his *Bibliotheca historica* (**5**. 33), and also Plutarch, in his *De garrulitate*, mentioned that the Celtiberians made steel of great hardness by burying plates of iron under the earth until the weaker part of the iron was consumed by rust, and using the part which remained for making their weapons. The process is mentioned by E. Swedenborg,[1] R. Watson, and J. Beckmann as a custom in use in Japan ; W. W. Campbell and E. E. Thum observed that some ancient specimens of Grecian iron were really steel.

The products of the bloomery furnaces must have frequently furnished mild steels (the processes indicated in connection with the history of the extraction of iron in India and Africa furnished steel) ; and steel was the product of the Catalan forge. Processes were described by S. Lucas,[2] D. Mushet, J. I. Hawkins, H. Larkin, H. Tholander and P. Hörden, E. Humbert and A. Hethey, and W. E. Newton for making steel by reducing ores rich in iron in crucibles, etc., along with carbonaceous matters. J. Percy said that more recent experiments on the subject often gave excellent products, but it was not found possible to ensure uniform results. According to R. Jenkins, the earliest definite reference to the production of steel in England occurs in the *Victoria County History of Sussex*, where it records that John Glade in 1513 held a tenement called *A Forge of Steel* in Ashdown Forest, Sussex. In 1525 this forge passed to John Bowley, who held it in 1548. M. Sudhoff said that the term *steel* first appears in the *Codex medicus Hertensis—ferrum quod stahal dicitur—* between the ninth and twelfth centuries. E. O. von Lippmann, and O. Schrader said that the word *steel* appears in all the German dialects—*Stahal* in Althochdeutsch ; *stahel, stachel,* or *stâl* in Mittelhochdeutsch ; *stâl* in Altnordisch ; *steel* in English ; *stalle* in Lapland ; and *stalē* in Slavish.

Additional observations on the development of the steel industry were made by J. O. Arnold,[3] P. Barnes, M. Bazin, L. Beck, C. Benedicks, G. Bresson, G. Broling, H. H. Campbell, L. Campredon, F. L. von Canerin, C. Chômienne, L. von Crell, H. V. Collet-Descotils, R. M. Daelen, H. Damemme, J. H. Darby, E. Darmstaedter, A. Delesse, I. B. J. Dessoye, W. Eilender, O. Evenstadt, F. A. A. Eversmann, J. François, P. A. Gadd and G. Korsemann, E. Garuffa, L. E. Gruner, R. A. Hadfield, J. H. Hall, F. W. Harbord, F. W. Harbord and J. W. Hall, C. F. A. Hartmann, J. Heaton, H. M. Howe, B. F. J. Hermann, H. Horne, P. S. Ihlström, J. S. Jeans, C. J. B. Karsten, L. Knab, F. Kohn, E. F. Lake, C. Lan, H. C. Landrin, H. Leobner, D. Little, E. Marché, E. Matheson, J. A. Mathews, W. Metcalf, L. B. Guyton de Morveau, B. Neumann, M. W. Newfeld, H. Noble, F. Overman, C. Palhem, W. Page, J. J. Perret, P. G. F. le Play, M. Rambourg, R. A. F. de Réaumur, J. Rosenreich-Diffrage, M. de Rozière, H. Rupe and F. Müller, H. Saemann, B. D. Saklatawalla, P. G. Salom, C. W. von Siemens, T. P. Smith, D. Tiselius, P. R. von Tunner, G. Turner, O. Vogel, J. B. Walker, T. Webster, K. Wittgenstein and A. Kurzwernhart.

For the direct production of steel in electric furnaces, *vide infra*. The old process of carburizing wrought iron by the cementation process has been practised from the Middle Ages up to the present time. The principles behind the process are described in a special section below. The bar-steel obtained by the cementation process was never homogeneous, and the same remark applies to steel made by several other processes. B. Huntsman found that homogeneous steel could be prepared by fusion in crucibles and subsequently casting the metal into ingots— **cast steel** or **crucible steel.** B. Huntsman's process was devised about 1700, and he melted blister-steel, cast it into ingots, and rolled it into bars. B. Huntsman's process was also described by P. G. F. le Play, and J. Percy. H. St. C. Deville and H. Caron reported on a process for melting the steel in reverberatory furnaces. One practical difficulty turns on preventing the metal changing its composition by contact with carbonaceous fuel. The manufacture of crucible

steel or cast steel was improved by J. M. Heath, who introduced some manganese carbide, or a mixture of manganese oxide and carbonaceous matters, along with the blister-steel. The resulting cast steel could be welded. T. Webster has discussed some litigation in connection with the patent rights. W. Reynolds also patented the addition of manganese to cast iron, or to cast iron for its conversion into steel. The crucible process was discussed by J. Bischoff, A. Ledebur, F. T. Sisco, J. A. Coyle, H. G. Manning, J. J. Mahon, F. Wüst, J. M. Gledhill, R. H. Probert, G. Hofer, F. C. G. Müller, J. Henrotte, R. A. Hadfield, D. Flather, A. Stotzer, C. Otto, R. F. Böhler, A. Harpf, O. Thallner, A. Brand, J. B. Johnston, S. Johnson, C. Casper, H. Seebohm, P. Oestberg, M. Boeker, etc.

In 1722 R. A. F. de Réaumur [4] prepared steel by melting together a mixture of wrought iron and cast iron. He said :

> It is, indeed, possible to fuse old scrap, points of nails, etc., in molten pig-iron. Such an addition of iron to the mixture causes it to lose its fusibility more quickly, and the period during which it remains in the molten state is shortened. A less quantity of the sulphurous constituents is evolved from the parts nearest to the surface. The iron takes up those which are given off by the fire, and the metal thus becomes converted into steel. By this means I have succeeded perfectly in making steel in an ordinary hearth by mixing sometimes one-quarter and sometimes one-third of iron with the pig-iron.

D. S. Price and E. C. Nicholson, G. Brown, and C. Attwood also patented processes for the same thing. M. Lister cited an obscure passage in Aristotle's Μετεωρολογικά referring to the conversion of iron into steel, and a process in which wrought iron is converted into steel by keeping it immersed in molten cast iron has been described by V. Biringuccio, G. Agricola, M. Lister, and others, as being well-known and practised in the sixteenth century ; and a reference in Pliny's *Historia naturalis* (**34**. 14) is taken to mean that the same process was in use at the beginning of our era. R. A. F. de Réaumur also described the same process.

There are several processes for the manufacture of steel by the decarburization of cast iron. In the old fining hearth the metal was heated with charcoal in a blast of air, while the cake of metal was covered with liquid cinder. With slight modifications the product may be either steel or wrought iron, as desired. The process as formerly conducted in Siegen, Carinthia, and Styria was described by P. R. von Tunner,[5] C. J. B. Karsten, and J. Percy. The decarburization of cast iron by cementation, that is, by heating it in contact with iron oxide, is discussed below ; while F. Uchatius proposed fusing the cast iron in contact with iron oxide or other substances capable of yielding oxygen. The operation more or less modified was described by J. and C. Wood, J. Wood, D. Mushet, M. de Rostaing, C. Peters, W. Spence, W. Spielfield, M. Lane, J. Paulis, etc. J. R. Bréant also, in 1824, said that he believed that it would be possible to produce steel in reverberatory furnaces by a process analogous to that of puddling. According to P. R. von Tunner, the process was employed in Styria for a short time. According to A. Delvaux de Fenffe, puddled steel was prepared in Bavaria, etc., about 1846. The process was also patented by E. Riepe, and described by C. Lan, G. Parry, W. W. Collins, B. Kerl, and J. Percy.

As in the case of puddling for wrought iron, various additions have been recommended with the idea of accelerating the process of decarburization. C. Schafhäutl's mixture of brown iron ore and common salt was discussed by P. R. von Tunner, and L. E. Gruner ; and J. Heaton's use of sodium nitrate for oxidizing the carbon was discussed by W. H. Miller, R. Mallet, D. Kirkaldy, W. Fairbairn, W. H. Williams, L. E. Gruner, and B. H. Paul. R. Mushet employed chromates or chromic oxide in place of manganese dioxide as an oxidizing agent ; J. E. Sherman, potassium iodide ; J. Henderson, fluorspar ; V. Gallet, a paste made of limestone, clay, resin, soot, charcoal, sodium carbonate and chloride, and manganese dioxide.

In 1855 J. G. Martin [6] obtained a patent for the manufacture of steel by the partial decarburization of cast iron by blowing air through the molten metal. W. Kelly, also, noticed that when cold air from the tuyères impinged on white-hot

iron, the iron became hotter instead of colder, and in 1857, W. Kelly patented a process of purifying pig-iron by blowing atmospheric air through the molten metal. Meanwhile H. Bessemer developed a process for converting pig-iron into steel by blowing air through a crucible full of the molten metal. A. Galy-Cazalat, in his French patents between 1851 and 1858, mentioned the refining of pig-iron by blowing a current of steam through the molten metal, but he did not allude to the refining of the metal by a current of air, so that the claims that have been made that he anticipated this process have not been established. There has been a controversy on the origin of H. Bessemer's process—H. Bessemer, R. W. Hunt, J. N. Boucher, J. Cournot, S. Jordan, E. Riley, R. H. Thurston, J. D. Weeks, H. M. Howe, etc.—and this was summed up by the *Engineer :*

> The Bessemer process is not a theory, it is an art. It is not one invention but fifty. W. Kelly's cupola did not anticipate the Bessemer converter as fully as Newcomen's engine did the modern triple-expansion engine. For Newcomen's engine could work ; it had an economical value ; it revolutionized the practice of mining.

The process of H. Bessemer was at first successful with Swedish pig-iron, which had a high proportion of manganese and a small proportion of phosphorus ; the process failed with English pig-iron, which was lower in manganese and higher in phosphorus. The product in the latter case was always red-short. The trouble was overcome by adding some spiegeleisen in accord with the patent of W. Reynolds, or of R. F. Mushet. It then became possible to manufacture low carbon steels—the so-called **Bessemer steels**—by the process. In **Bessemer's process,** 10 to 15 tons of molten pig-iron are run into a large egg-shaped vessel called the *converter.* The con-

FIG. 35.—Section of the Bessemer's Converter.

verter can be tilted into any required position. It is provided with holes at the bottom through which a powerful blast of air can be blown. It is tilted horizontally while the molten metal is being poured in. The blast is turned on, and the converter is swung into a vertical position. The converter is made of wrought-iron plates, and lined with a suitable refractory material. A general idea of the structure of a converter can be gathered from Fig. 35, which gives a vertical section, showing the air nozzle leading to a wind-box from which a powerful blast of air in 150 to 200 fine jets passes through the mass of molten metal. The temp. rises owing to the heat evolved by the oxidation and com-bustion of the impurities—the carbon, sulphur, and manganese. The carbon forms carbon monoxide, which burns at the mouth of the converter. The flame is accompanied by a brilliant spectacular shower of sparks. The other oxides form a slag with the furnace lining. Experience and the appearance of the flame tell the operator when to stop the blast. In about 10 or 15 mins. nearly all the carbon and most of the impurities are burnt out, and iron, equivalent to wrought iron, remains. The molten product is changed into steel by adding the right pro-portion of carbon, manganese, etc., as desired. Usually the right amount of spiegeleisen is then added to make a metal of definite composition. The blast is again turned on for a moment, and the metal is then cast into moulds to form blocks of Bessemer's steel.

The process was discussed by R. Akerman, H. Bansen, P. Barthel, M. Belman, G. Bergström, L. E. Boman, W. Borchers, F. G. Bremme, A. Brovot, H. H. Campbell, C. Canaris, W. M. Carr, F. J. R. Carulla, C. A. Casperson, W. J. Clapp and J. Griffiths, J. Cournot, R. M. Daelen, J. Deby, L. Delacuvellerie, E. Demenge, E. Faust, V. Firket,

J. Flohr, R. Frerich, H. van Gendt, F. Grassmann, C. Gonner, L. Hacha, J. Hardisty, A. P. Head, C. E. Heurteau, E. Heyrowsky, G. Hilgenstock, F. Hilton, O. von Hingenau, H. L. Hollis, E. Holz, H. M. Howe, R. W. Hunt, A. von Ihering, W. H. Jacques, A. Johansson, S. Jordan, O. von Keil, F. Kintzle, W. E. Koch, J. Lagerwall, E. Langhein- rich, F. Laur, K. Leo, L. Lewis, F. W. Lürmann, R. S. McCaffrey, C. Malz, P. N. Mathur, J. R. Miller, F. C. G. Müller, F. Munichsdorfer and E. A. Frey, J. B. Nau, S. Peters, C. Pixis, A. Pourcel and F. Valton, E. Priwoznik, A. W. Richards, A. de Riva-Berni, T. W. Robinson, C. Rott, H. J. van Royden, F. Schröder, E. Schrödter, J. Seigle, R. von Seth, A. Simonson, J. Smeysters, G. J. Snelus, K. Sorge, M. Stammschulte, W. Stercken, W. Stöckl, O. Thiel, J. Thieme, M. von Tittler, F. E. Thomson, R. H. Thurston, F. Toldt, A. Tropenas, L. Unckenbolt, B. Versen, O. Vogel, J. Wagner, G. B. Waterhouse, H. Wedding, J. D. Weeks, J. G. Wiborgh, and C. D. Wright.

In H. Bessemer's process the lining of the converter was made of siliceous material—say, ganister blocks with a bond of a mixture of fireclay and coke-dust. Owing to the acid character of the lining of the converter, this process is called the **acid Bessemer process**, to distinguish it from the so-called **basic Bessemer process**, in which the lining is of basic material—generally blocks made from well-burnt dolomite. The blow occupies about 12 mins. and three stages can be recognized : (i) The *sagging period* occupies about 4 mins. Most of the silicon burns to silica, forming a siliceous slag—$FeSiO_3$ and $MnSiO_3$. The flame is not very luminous, and it is attended by scintillating sparks. (ii) The *boiling period* occupies about 6 mins. The silicon continues to burn, and the carbon forms carbon monoxide, and molten metal boils violently. The flame is very luminous and is attended by showers of sparks. (iii) The *fining period* occupies about 2 mins. The carbon continues burning, and iron is oxidized. The flame becomes less luminous and drops, indicating the end of the blow.

The subject was investigated by T. Rowan, R. Akerman, R. Addie, E. Herzog, S. Jordan, P. Kupelwieser, F. C. G. Müller, A. von Kerpely, F. Kessler, W. J. Campbell, A. Tamm, E. Tschernoff, etc. According to G. J. Snelus, the composition of the gases during a 14-minutes blow was as follows (hydrogen by difference) :

	2	4	6	10	12	14 mins.
CO_2	9·12	8·57	8·05	3·58	2·38	1·34
O_2	0·92	0·00	0·00	0·00	0·00	0·00
CO	0·06	3·95	4·58	19·59	29·44	31·11
H_2	0·00	0·88	2·00	2·00	2·16	2·00
N_2	90·31	86·58	85·37	74·83	66·02	65·55

F. Kessler gave for the analyses of the metal at different stages of the blow :

	Pig-iron	After 4 mins.	Beginning 2nd period	Middle 2nd period	End before adding spiegel	Finished product
Free carbon	2·52	0·14	0·04	0·01	0·00	0·00
Combined C	1·06	3·65	3·53	2·47	0·29	0·45
Silicon	1·875	1·200	0·648	0·067	0·021	0·083
Phosphorus	0·100	0·106	0·096	0·097	0·109	0·104
Sulphur	0·372	0·069	0·061	0·077	0·113	0·080
Manganese	1·04	0·23	0·08	0·06	0·05	0·34

F. Kessler's results show that the amount of phosphorus in the steel decreases in the middle stage of the process, but increases both in the commencement of the blow—owing to the relatively greater oxidation of the other substances—as well as at the end, when it is, in part at least, taken up again from the slag. Sulphur decreases rapidly at first, but then increases in the middle stage, up to the addition of the spiegeleisen, for the reason that a portion of it which in the first stage went into the slag in the form of metallic sulphides was afterwards again taken up by the iron. So long as the manganese is being oxidized and removed from the iron the percentage of sulphur in the iron diminishes ; but as soon as the iron is free from manganese, it again takes up a portion of the sulphur contained in the slag. When the spiegeleisen is added and the blow recommenced, the sulphur again diminishes ; and if the first slag (which is sulphurous) could be removed, then it would be possible to use brands of iron which are known to contain sulphur for

making Bessemer steel. The various analyses of the products at different stages of the blow show that there is an analogy between the chemical changes in the Bessemer process and in puddling, although the process of oxidation of silicon and carbon is not always the same. According to F. C. G. Müller,

It is probable that during the first few minutes of the blow, the silicon is consumed, raising the temp. of the bath 200°. This increase, however, impairs the affinity of silicon for oxygen, so that during the second period then following its elimination is of secondary importance only, while the oxidation of carbon, the formation of carbonic oxide, becomes the principal reaction, as the large flame and the splashing tend to show. The temperature remains constant. Without manganese the bath would cool, and thus the oxidation of silicon would be resumed. The burning manganese escapes as Mn_3O_4, in the shape of brown clouds; it does not enter the slag, because little silica is forming. The oxidation takes place chiefly through the agency of oxide of iron, which is dissolved in the bath, the reaction being limited, however, to a low temperature. An entire cessation of the oxidation of silicon gives rise to the most violent splashing. The length of this period increases with an increase in the percentage of carbon, and therefore it is absurd to aim at a high percentage of carbon in the Bessemer process. As soon as the flame grows smaller and transparent, and the noise ceases, the third short period begins, during which, in consequence of a considerable increase in the amount of oxide in the bath, the silicon is again more energetically consumed. A slag is formed which is richer in iron, and which in colour approaches brown. A dip sample taken at this period serves as a good indicator for the state of the process. The silicon is consumed rapidly after the addition of spiegel, the cause being, perhaps, the cooling of the bath by the colder metal. Besides the large amount of silicon consumed during the last period, a slow combustion of the residual graphite takes place also. . . . The composition of the slag is SiO_2, 43·73; MnO, 45·41; FeO, 9·04; and Al_2O_3, 1·99. According to A. Ledebur, the slags formed before the addition of spiegeleisen in the acid Bessemer process have the composition:

								3	6	8 mins.
Silica	.	.	.	.	.	.	.	53·44	57·80	55·76
Alumina	.	.	.	.	.	.	.	1·84	1·94	1·58
Ferrous oxide	.	.	.	.	.	.	.	20·24	17·04	18·48
Manganous oxide	.	.	.	.	.	.	.	23·90	22·80	22·23
Earths	.	.	.	.	.	.	.	0·44	0·46	0·39

The theory and thermochemistry of the process were discussed by W. N. Hartley, H. Schenck, H. Hermann, R. von Seth, J. Sullivan, J. W. Haulman, B. Osann, R. S. McCaffrey, L. C. Glaser, G. K. Burgess, F. T. Sisco, J. W. Richards, G. Butz, H. Bansen, K. Thomas, and H. Ponthière; the temp. of the converter, by R. A. Hadfield, F. E. Bash, and A. Cornu-Thénard.
Fig. 36.—The Rates of Oxidation of Manganese, Silicon, and Carbon in the Bessemer Process.

F. Fischer showed that when atm. air is passed through the molten bath, all the substances which come in contact with oxygen will burn, so that primarily only direct combustion occurs. The oxides formed then interact with the other constituents of the bath.

There is first $C + CO_2 = 2CO - 3880$ Cals., which sensibly cools the bath. When pig-iron is fused with silica or silicates, silicon and carbon monoxide are formed: $2C + SiO_2 = 2CO + Si - 16,200$ Cals. This reaction requires, however, such a considerable amount of heat that it probably only takes place at very high temperatures. On the other hand, the reactions $Si + CO_2 = SiO_2 + C + 12,320$ Cals. and $Si + 2CO = SiO_2 + 2C + 16,200$ Cals. yield much heat and are consequently pronounced in their action. Manganese behaves similarly: $Mn + CO_2 = MnO + CO + 2680$ Cals.; $2Mn + CO_2 = 2MnO + C + 9240$ Cals.; and $MnO + SiO_2 = MnSiO_3 +$ about 3500 Cals. The combustion of the manganese in carbon dioxide and its passage into the slag are therefore also accompanied by a considerable evolution of heat. The following reaction can also very readily take place:

$Mn+CO=MnO+C+6560$ Cals. Silicon and manganese do not therefore protect the carbon from combustion, and they reduce again the products of combustion of carbon, and so cause the latter to pass again into the iron. The action of the iron itself is much weaker. At a red-heat : (1) $3Fe+4CO_2=Fe_3O_4+4CO-810$ Cals. ; (2) Fe_3O_4+4CO $=3Fe+4CO_2+810$ Cals. ; and at a very high temperature (3) $Fe_3O_4+8CO=3Fe+2C+6CO_2$ $-10,710$ Cals. This last reaction is accompanied by such a large absorption of heat that it cannot be very pronounced.

The results of P. Kupelwieser with manganiferous pig-iron were summarized by W. N. Hartley, in a diagram resembling Fig. 36. The composition of the pig-iron was : 3·46, Mn ; 3·94, C ; and 1·96, Si. One of the first changes is the passage of free carbon to combined carbon, which is illustrated by the dotted line in the diagram. According to F. W. Harbord and J. W. Hall, the following may be regarded as typical analyses of acid Bessemer steel :

	Combined C	Si	S	P	Mn	As
Soft steel .	0·10–0·15	0·02–0·06	0·03–0·08	0·04–0·08	0·40–0·80	0·02–0·06 per cent.
Rail steel .	0·32–0·55	0·04–0·08	0·05–0·08	0·06–0·08	0·60–1·00	0·02–0·08 per cent.

By using specially selected pig-iron the phosphorus and sulphur may be reduced below these limits. The composition of the pig-iron used in the acid process is typically :

Combined C	Free C	Si	S	P	Mn	As
0·40	3·20	2·25	0·05	0·05	0·50	0·03 per cent.

The phosphorus, arsenic, and sulphur should be as low as possible and not exceed 0·06 per cent. ; while the manganese should not exceed 1 per cent. The carbon may be between 3·2 and 4 per cent. The silicon should be between 2·0 and 2·5 or 3·0 per cent. A. Ledebur found that the chromium and vanadium in pig-iron are thus affected by the Bessemer treatment :

	C	Mn	Cr	V
Before blow . .	2·518	0·792	0·073	0·072 per cent.
After blow . .	0·080	0·360	0·013	0·000 per cent.

H. Reuss discussed the liquation phenomena in a cast Bessemer steel roll weighing 7 tons.

The use of the spectroscope for fixing the end of the operation was discussed by E. Tschernoff, P. R. von Tunner, J. M. Silliman, T. Rowan, A. Greiner, etc. According to H. E. Roscoe, A. Lielegg, P. Kupelwieser, and J. S. Parker, the spectrum of the Bessemer flame is characterized by bands of carbon or carbon monoxide, while, according to R. Simmler, A. Greiner, J. Brunner, A. von Lichtenfeld, and H. Wedding, the spectrum is not due to carbon or carbon monoxide, but rather to manganese and other elements in pig-iron ; and M. Watts said that the spectrum is not due to carbon, carbon monoxide, or manganese, but rather to manganic oxide. According to M. Watts, the difference in the spectrum observed in different works is due to the temp. and the composition of the metal under treatment. In the first or slagging period the lines of the alkali metals—sodium, potassium, and lithium—were unreversed on a bright continuous spectrum of carbon monoxide ; the C-line and apparently the F-line of hydrogen were seen reversed during a snowstorm. In the second or boiling period bands of manganese overlying the continuous spectrum of carbon monoxide were prominent. There are lines of carbon monoxide, manganese, and iron, and also those of the alkali metals. In the third or fining period the lines of iron are not so strong as in the boiling stage and they are not so well-defined ; indeed, some of the short lines disappear. The lines of the alkali metals are visible. The bands of manganese oxide may be present ; if so, they are obscured by the continuous carbon monoxide spectrum. No absorption bands were seen, no nitrogen bands, nor bands of calcium and magnesium oxides, neither did the lines of these metals appear. There is no trace of cobalt, nickel, chromium, or copper ; certain carbon bands overlie those of manganese and are recognized by measurements of their edges. Some of the lines not identified by M. Watts were found to be iron lines, others belong to manganese. M. Watts

observed the red line of hydrogen during wet weather. W. N. Hartley identified the spectral lines of calcium, rubidium, cæsium, copper, silver, thallium, and gallium in the flame of Bessemer's converter.

It will be observed that sulphur and particularly phosphorus are not removed by the acid Bessemer process. In 1878, S. G. Thomas showed that if the converter be lined with a basic material, say dolomite, and the blast be continued a little longer, the oxides of phosphorus, sulphur, and silicon which are formed are absorbed by the furnace lining. Some lime is put into the converter near the beginning of the blow to furnish the base necessary for the production of the slag, and to protect the basic lining of the converter from undue corrosion by slagging. Otherwise the operation is conducted as just indicated. S. G. Thomas developed the process in co-operation with P. C. Gilchrist, so that in England the process came to be called **Thomas-Gilchrist's process** ; in Germany it is called *Thomas's process*, and in America the *basic Bessemer process*. The process was discussed by H. Schulz and J. Schönava, A. Herberholz, C. W. Ljunggren, A. Brovot, V. Harbord, C. Longenecker, F. M. Feldhaus, E. Mathesius, F. Grassmann, F. Kintzle, J. von Ehrenwerth, G. Bresson, H. Schuphaus, A. Wasum, J. Massenez, G. Hilgenstock, A. Spannagel, etc. According to F. W. Harbord and J. W. Hall, the following may be regarded as typical analyses of basic Bessemer steel :

	Combined C	Si	S	P	Mn	As
Soft steel .	0·08-0·15	trace	0·03-0·08	0·04-0·08	0·40-0·80	0·02-0·06 per cent.
Rail steel .	0·32-0·55	0-0·02	0·05-0·08	0·06-0·08	0·60-0·100	0·02-0·06 per cent.

With special care in the selection of the pig-iron the impurities may be reduced below these limits, and vice versa. The pig-iron for the basic process has the typical analysis :

Combined C	Free C	Si	S	P	Mn	As
3·40	0·20	1·00	0·05	3·00	2·00	0·03 per cent.

Iron with over 1 per cent. silicon may be used, but the silicon is preferred low. The phosphorus may be between 2·5 and 3·5 per cent. The lower the sulphur and arsenic the better, and they should not exceed 0·06 per cent. A. Tamm made analyses of the gases at different stages of the blow ; C. Scheibler, E. Steinweg, G. Hilgenstock, and E. Schrödter discussed the slags—*vide* **3.** 24, 25, *et seq.* R. Finkener gave for the composition of the metal and of the corresponding slags at different stages of the basic Bessemer process and after the addition of spiegeleisen :

Time .	.	2' 46"	5' 21"	8' 5"	10' 45"	13' 28"	15' 13"	19' 14"	19' 49"	After spiegel

According to W. N. Hartley and H. Ramage, the phenomena occurring during the blow in the basic Bessemer process differ considerably from those of the acid process. They said :

First, a flame is visible from the commencement of blowing, or as soon as the cloud of lime-dust has dispersed. We conclude that the immediate production of this flame is caused by carbonaceous matter in the lining of the vessel, that its luminosity is due partly to the volatilization of the alkalies, and to the incandescence of lime-dust carried out by the blast. Secondly, volatilization of metal occurs largely at an early period in the blow,

and is due to the difference in composition of the metal blown, chiefly to the smaller quantity of silicon. There is practically no distinct period when siliceous slags are formed in the basic process, and metals are volatilized readily in the reducing atmosphere, rich in carbon monoxide. Thirdly, a very large amount of fume is formed towards the close of the second period. This arises from the oxidation of the metal and of phosphorus in the iron phosphide, being productive of a high temp., but little or no carbon remaining. The flame is comparatively short, and the metallic vapours carried up are burnt by the blast. Fourthly, the over-blow is characterized by a very powerful illumination from what appears to be a brilliant yellow flame : a dense fume is produced at this time composed of oxidized metallic vapours, chiefly iron. These particles are undoubtedly of very minute dimensions, as is proved by the fact that they scatter the light which falls on them, and the cloud casts a brown shadow, and, on a still day, ascends to a great height. The spectrum is continuous, but does not extend beyond wave-length 4000 A. This indicates that the source of light is at a comparatively low temp., approaching that of a yellowish-white heat. We conclude, therefore, that the light emanates from a torrent of very small particles, liquid or solid, at a yellowish-white heat. The " flame " can have but little reducing power at this stage, and this, together with its low temp., accounts for the very feeble lines of lithium, sodium, potassium, and manganese seen in the photographs or by eye observations. Fifthly, the spectra of flames from the first stage of the basic process differ from those of the acid process in several particulars. The manganese bands are relatively feeble, and lines of elements not usually associated with Bessemer metal are present. Both the charges of metal and of basic material contribute to these. Lithium, sodium, potassium, rubidium, and cæsium have been traced mainly to the lime ; manganese, copper, silver, and gallium to the metal. Other metals, such as vanadium and titanium, are not in evidence, because they do not yield flame spectra ; they, together with chromium, pass into the slag in an oxidized state.

In 1862, C. Attwood [7] patented a process for manufacturing steel from a mixture of wrought iron and cast iron with some spiegeleisen—*vide supra*. He employed a regenerative open-hearth or reverberatory furnace designed by C. W. von Siemens. The reverberatory furnace has a roof formed of silica bricks sloping towards the centre, with a shallow rectangular trough as hearth. The process was too costly. The process was also tried in France in 1863, at the works of P. and E. Martin, Sireuil, where steel was manufactured in the Siemens furnace by dissolving scrap wrought iron in a bath of cast iron with a suitable addition of manganese and carbon at the end of the operation. The process in this form assumed no commercial importance, but when C. W. von Siemens applied the regenerative furnace to the decarburization of cast iron by the use of iron ore, with or without the use of iron or steel scrap, the process developed rapidly as the **open-hearth process** or the **Siemens-Martin's process.** In the original process of C. W. von Siemens the oxide ore was added to the molten pig-iron, the so-called *pig and ore process* ; P. and E. Martin added scrap without ore to the molten pig-iron, the so-called *pig and scrap process*. E. Maurer and W. Bischof discussed the history of the open-hearth process.

According to L. Guillet, at Kladno, about 1830, successful attempts were made to dephosphorize iron by using a ferruginous lining with a puddling-furnace ; and in 1859, L. E. Gruner commented on the subject in connection with puddled steel. In 1869, E. Muller patented the use of magnesia linings for Bessemer converters and Martin's furnaces so as to eliminate sulphur. C. M. Tessié du Motay, in 1872, and A. Lencauchez, in 1875, reverted to the dephosphorizing effect of magnesia linings ; and in 1878, S. G. Thomas and P. C. Gilchrist announced the discovery of their basic process for the manufacture of steel.

Molten pig-iron is run directly into the furnace, or else a charge of, say, 5 tons of pig-iron is put on the bed of the furnace, and when it is melted down iron ore broken to the size of ordinary road-metal is thrown in. This makes the molten metal " boil " vigorously ; more ore is added in successive portions so as to keep up a good " boil." It is then allowed to stand for a short time to permit as much as possible of the iron to work out of the slag. Broken limestone or quicklime may be added at intervals during the process to assist in separating the iron from the slag. The molten iron is maintained in a fluid condition to allow samples to be removed and tested. Additions of wrought scrap or pig-iron may be made to adjust the metal to the desired temper. Ferro-manganese or spiegeleisen is then added,

and as soon as this is all melted the charge is tapped. A 5-ton furnace is a very small one; some hold up to 125 tons. The average capacity is about 70 tons per heat.

The furnace is heated by producer gas. Both the gas and the secondary air for the combustion of the gas are pre-heated, so that a very high temperature can be obtained. A general idea of the process can be gathered from Fig. 37, which shows a section through the hearth. The gas and air burn on the left; the flue gases travel down the flue on the right and in doing so heat up two chambers below. The direction of the burning gas is then reversed. Gas and air pass separately through the hot chambers, and the flue gases heat up another pair of chambers below the hearth. The direction travelled by the burning gas is reversed about every half and in some cases every quarter of an hour, and the heat of the flue gases is utilized in warming-up chambers through which the unburnt gas and air will pass later on. The furnace is called *Siemens' regenerative furnace*.

If the bed of the furnace is made of siliceous materials—*acid open-hearth process*—the proportions of carbon, silicon, and manganese are reduced during the treatment, but the amounts of sulphur and phosphorus remain fairly constant. In the *basic*

being cooled.   being heated.
FIG. 37.—Section through the Open-hearth Furnace.

</div>

open-hearth process the furnace is bedded with, say, dolomite, and there is a steady fall in the amount of phosphorus during the treatment, just as was the case with the basic Bessemer's process of S. G. Thomas and P. C. Gilchrist.

About 1908, the output of steel by the open-hearth process surpassed that produced by Bessemer's process; and although the former is slower, it permits a far greater control of the reactions involved and of the composition of the finished metal. It also allows a greater variety of phosphatic pig-irons to be treated.

The open-hearth process has been discussed by P. Acker, R. Akerman, W. Alberts, T. N. Armstrong, C. H. F. Bagley, H. Bansen, W. P. Barba and H. M. Howe, A. Barberot, W. J. Beck, R. Becker, A. Berglöf, F. Bernhardt, I. A. Billiar, E. Blau, C. Bohlin, A. Bosser, G. R. Boyd, H. Braune, J. A. Brinell, C. Brisker, G. B. Bruno and G. Delbart, A. Byström, J. W. Cabot, H. H. Campbell, C. Canaris, W. M. Carr, C. A. Casperson, S. Casson, W. P. Chandler, J. Christie, H. O. Chute, D. Clark, F. Clements, M. J. Conway, S. J. Cort, E. Cotel, C. C. de Coussergues, F. J. Crolius, H. Crowe, R. M. Daelen. R. M. Daelen and L. Pozczolka, J. Davis, B. Dawson, G. Desprit, C. Dichmann, A. M. Dick and C. S. Hadley, A. N. Diehl, E. Diepschlag, J. von Ehrenwerth, H. de Estève, A. L. Field, F. Fiorelli, R. Frerich, R. Furness, L. Gautier, R. Genzer, M. L. Gerard, P. C. Gilchrist, H. Gille, A. Gouvy, F. Grassmann, H. G. Graves, J. A. de Grey, W. E. Griffiths and C. E. Meissner, H. Groeck, E. Günter, F. W. Harbord and J. W. Hall, J. Hartshorne, H. S. Hastings, A. Herberholz, H. Hermanns, C. H. Herty, C. H. Herty and co-workers, E. Herzog, H. D. Hibbard, N. F. Hindle, G. Hofer, O. Holz, J. K. Hoyt, H. Illies, E. J. Janitzky, E. R. Jette, R. Johannsson, A, Jung, P. Kahnert, W. Keen, R. T. Kent, E. Killing, C. D. King, C. L. Kinney, P. Klein, J. L. Klindworth, K. Köhler, F. Kofler, S. G. Koon, K. Kreiss, P. Kupelweiser, T. G. Kus, E. Langheinrich, B. M. Larsen, H. W. Lash, F. E. Lathe, M. Lencauchez, F. Lepersonne, W. Lister, E. de Loisy, E. Lubojatzky,

	Mn	0·34	0·17	—	—	—	—	—	0·43

The symbol * means that ore was added, and † that sand was added. During the melting period, when solid pig and scrap was used, the products of combustion— either as free oxygen or carbon dioxide—act on the metal to oxidize carbon, silicon, and manganese, but when the charge is completely melted and covered with a layer of molten slag, oxidation occurs through the abstraction of oxygen from some of the constituents of the slag. If the ferrous oxide becomes reduced by this means, the slag becomes too acidic and viscid, and it is necessary to add more ferric oxide in the form of iron ore. H. Allen represents the loss of carbon by the molten metal by a curve resembling Fig. 38 ; whilst the changes which take place during the working of a charge in a basic furnace are illustrated by Fig. 39.

Observations on the subject were made by H. H. Campbell, C. H. Herty and co-workers, F. Kollmann, G. Mehrtens, H. Schenck, F. Stille, H. Styri, and K. Thomas ; and in the basic furnace, by R. Back, H. Bansen, W. J. Beck, H. M. Boyston, W. D. Brown, G. K. Burgess, H. H. Campbell, W. P. Chandler, T. P. Colclough, S. Cornell, C. C. de Coussergues, A. S. Cushman, E. Damour, M. Deslandes, G. A. Dornin, J. B. Ferguson, A. L. Field, G. Fisk, R. Fornander, R. Furness, J. M. Gaines, K. Gierdziejewsky, M. Groume-Grjimailo, J. Guyot, F. W. Harbord, A. Harrison and R. V. Wheeler, W. Heil, W. M. Henry and T. J. McLoughlin, A. Herberholz, H. Hermanns, C. H. Herty, C. H. Herty and co-workers, E. Herzog, E. Houbaer, W. Hülsbruch, K. Huessener, E. R. Jette, A. Jung, E. Killing, C. L. Kinney and G. R. McDermott, S. P. Kinney, A. B. Kinzel and J. J. Egan, K. Köhler, B. M. Larsen, B. M. Larsen and J. W. Campbell, E. de Loisy, E. Lubojatzky, A. McCance, P. M. Macnair, G. Mars, R. Mather, F. A. Mathewman, F. A. Mathewman and A. Campion, E. Maurer and S. Schleicher, E. Mayer, G. Mehrtens, J. R. Miller, H. Monden, G. Neumann, E. Noaillon, P. Oberhoffer and co-workers, R. D. Pike, V. Polak, F. Sandelin, A. Schack, H. Schenck, S. Schleicher, W. Schmidhammer, H. Schmidt, H. Schmidt and W. Liesegang, C. Schwarz, H. See, H. W. Seldon, A. Silin, D. Sillars, F. T. Sisco, H. Styri, G. Tammann and co-workers, K. Thomas, M. Tigerschiöld, W. Trinks, C. W. Veach, G. B. Waterhouse, J. H. Whiteley, J. F. Wilson, J. T. Wright, F. Wüst, F. Wüst and J. Duhr, and B. Yaneske and co-workers. R. A. Hadfield measured the temp. of the furnace.   S. Schleicher studied the composition of the bath at different depths.

According to F. W. Harbord and J. W. Hall, the following are typical analyses of open-hearth steels :

		Combined C	Si	S	P	Mn	As
Acid	Soft steel	0·12–0·20	0·04–0·08	0·02–0·0б	0·02–0·06	0·40–0·60	0·02–0·06 per cent.
	Rail steel	0·20–1·50	0·04–0·35	0·02–0·06	0·02–0·06	0·40–1·00	0·02–0·06 per cent.
Basic	Soft steel	0·10–0·18	tr.	0·02–0·06	0·03–0·06	0·40–0·80	0·01–0·06 per cent.
	Rail steel	0·45–0·70	0·00–0·35	0·04–0·06	0·04–0·06	0·60–0·90	0·01–0·06 per cent.

By using special hæmatite pig-iron the phosphorus can be almost eliminated. Typical analyses of pig-iron for these processes are :

	Combined C	Free C	Si	S	P	Mn	As
Acid .	0·40	3·20	2·00	0·04	0·04	0·60	0·03 per cent.
Basic .	3·40	0·20	<1·00	0·05	<2·00	2·00	0·3 per cent.

The carbon for the acid process may vary from 3·2 to 4·0 per cent. ; the silicon should not exceed 2·50, and manganese, 1·00 ; and the lower the phosphorus, sulphur, and arsenic the better, but the percentage should not exceed 0·05 per cent. in each case.   For the basic process the silicon should be less than 1 per cent., and the phosphorus below 2·00 per cent., but some is used with about 3 per cent. of phosphorus.   If sulphur is low, the manganese may be less than 1 per cent., but if sulphur is high, more manganese may be necessary.   H. Schenck studied the manganese and phosphorus reactions in the basic process ; H. Schenck, H. D. Hibbard, and A. S. Thomas, the silicon ; and S. Schleicher, E. H. Saniter, A. Riemer, F. E. Thompson, F. Stille, J. E. Stead, K. Gierdziejewsky, H. Goldschmidt, W. G. Burman, J. Massenez, L. J. Ball and A. Wingham, etc., the sulphur.   R. M. Keeney, W. S. Hamilton, G. H. Jones, H. L. Geiger, A. C. Dalton, and L. Goldmerstein discussed the use of fluorspar in steel-making.

Numerous modifications of the open-hearth process have been devised.   In many of them the furnace is designed so that the hearth can be tilted and either metal or slag run off as desired.   Modifications have been discussed by F. W. Harbord and J. W. Hall, H. Wedding, B. Talbot, L. Unckenbolt, S. Surzycki, O. Simmersbach, J. H. Darby and G. Hatton, A. P. Head, J. Head, P. Eyermann, R. M. Daelen and L. Poczolka, H. Illies, O. Thiel, J. W. Cabot, A. Ledebur, H. M. Howe, A. E. Davies, etc.   R. B. Carnahan, and A. S. Cushman developed a method for preparing iron of a high degree of purity.   It has the trade-name **armco-iron.**   It was discussed by A. Sauveur—*vide infra.*

The application of **electric furnaces** to the manufacture of steel has developed along two directions.   Where electric power is cheap enough, electric heating has replaced the use of fuels like gas, so that ten years ago in Norway electric furnaces displaced open-hearth furnaces.   In other cases it has been found advantageous to

combine two operations, in which the steel is subjected to a preliminary treatment in the open-hearth furnace, and the liquid steel is then transferred to the electric furnace for the final purification—deoxidation, desulphurization, adjustment of carbon, and additions of other elements for the production of alloy steels. High-grade electric steel can be thus produced equivalent to high-grade crucible steels at a favourable cost. The use of a higher temp. and the maintenance of a clean reducing atmosphere are great advantages. With alloy steels the losses through oxidation are much less than in fuel-heated furnaces. Steel can be readily obtained from scrap metal without the use of pig-iron, and steel of a uniform and good quality can be produced from low-grade materials. The subject has been discussed by J. N. Pring,[8] etc.

One of the many forms of furnace designed by P. L. T. Héroult [9] is illustrated diagrammatically in Fig. 40. The furnace may be 16 ft. in diameter, and it has a plate-steel shell about an inch thick. It is lined for 4½ ins. with firebrick ; inside that is a lining of magnesite bricks, 9 to 13½ ins. thick ; and above that is a bed of burned magnesite, 13 ins. thick. The domed roof, 12 ins. thick, is of silica brick. The openings in the roof are for the three carbon electrodes, which are 20 ins. diam. and are carried by horizontal arms projecting over the furnace, and which can be adjusted by movable rods. Heavy copper cables and bars carry the current from the transformer. The bottom of the furnace is carried on toothed rockers and tracks so that the furnace can be tilted. The tilting gear is operated by a motor which tilts the furnace by means of a connecting-rod. The furnace is charged with, say, 25 tons of molten metal from the open-hearth or Bessemer furnace, and the current is switched on. The bottom of the electrode is adjusted with about three-quarters of an inch clearance from the surface of the slag. The alternating, 3-phase current has an amperage of about 6000

FIG. 40.—Héroult Electric Steel Furnace.

to 14,000 per phase, and a voltage of 110. The temp. rises from about 1510° with high-carbon steel to about 1650° with low-carbon steel. Limestone and iron oxide are added as desired. These materials form an oxidized slag for reducing the phosphorus down to about 0·008 per cent. The slag is then run off, and another mixture called a reducing slag is added. It consists of limestone, sand, fluorspar, and coke-dust. It deoxidizes and desulphurizes the metal. If desired, the proper amount of the alloy metals—manganese, nickel, chromium, or vanadium—is added, and the metal is ready for pouring after the slag has been run off. The whole operation occupies between 4 and 5 hrs. The reactions which occur in the basic process were discussed by F. T. Sisco, and W. E. Moore.

According to F. R. Eichoff, " it is impossible to heat a steel arc-furnace by utilizing the heat generated by the resistance of the thin layer of slag, or of the large cross-section of the bath. These resistances furnish only a few per cent. of the heat necessary in the furnace. . . . The heat cannot be obtained by the decreasing resistance offered by the slag as the temp. rises, or by utilizing the resistance of the bath. The slag layer is too thin, and the cross-section of the steel bath too large." The heat of the Héroult furnace is almost entirely derived from the heat of the arc formed between the electrodes and the bath. The ferric oxide added to the bath is reduced to ferrous oxide, and it distributes itself between the metal and the slag. The oxidizing slag contains about 40 per cent. CaO ; 26 to 29 per cent. FeO and MnO ; and up to about 4 per cent. P_2O_5. The oxidizing slag only affects

the sulphur to a small extent. A little sulphur dioxide may be formed by the reaction $FeS+2FeO=3Fe+SO_2$. When the reducing slag is introduced, the ferrous sulphide which is formed is distributed between the slag and the metal in accord with the partition law ; and similarly also with the manganous sulphide. The reaction with the slag may proceed : $FeS+CaO \rightleftharpoons CaS+FeO$; but at the same time the ferrous oxide is reduced : $FeO+C \rightleftharpoons CO+Fe$. The subject was discussed by T. Geilenkirchen, and B. Osann. The carbon in the reducing slag may form silicon carbide, calcium silicide, and calcium carbide. The latter compound explains the smell of acetylene from a cooled sample. The calcium carbide in the slag may react with the ferrous sulphide : $2CaO+3FeS+CaC_2=3Fe+3CaS+2CO$. According to W. Fielding, some silicon sulphide may be formed : $2FeS+FeSi$ $=3Fe+SiS_2$. According to C. C. de Coussergues, hydrogen dissolved in the steel is attacked by the calcium carbide : $CaC_2+H_2=CaC_2H_2$.

The electric furnaces are usually classed as arc-furnaces and resistance furnaces. (1) *The arc-furnaces* may have (i) a direct heating arc (*a*) in series between the electrodes and the metal, as in P. L. T. Héroult's furnace just described. Other examples are the furnaces of W. E. Moore,[10] C. H. von Baur,[11] V. Stobie,[12] E. F. Russ,[13] and C. A. Keller.[14] Or (*b*) one or more electrodes may be imbedded in the hearth of the furnace so that the current arcs across from one set of electrodes to the steel, and thence out through the furnace bottom, as in the furnaces of P. Girod,[15] C. A. Keller,[16] F. T. Snyder,[17] The Electro-Metals Co.,[18] H. Nathusius,[19] and J. Härden.[20] W. K. Booth,[21] and J. L. Dixon[22] discussed the Greaves-Etchells furnace, which, according to C. E. Moore, is going out of use in the United States. The arc-furnaces may have (ii) an independent arc, as in the furnace of E. Stassano,[23] and I. Rennerfelt.[24] According to C. E. Moore, these two furnaces are not now used in the United States. There are (2) *the resistance furnaces*, which operate (i) by induction,[25] as in the furnaces of Z. de Ferranti,[26] F. A. Kjellin, O. Frick,[27] W. Rodenhauser,[28] A. Hiorth,[29] and E. F. Northrup.[30] The induction furnace proposed by C. Hering,[31] based on the so-called Pinch effect, has not been commercially successful. (ii) Resistance furnaces of the type proposed by G. Gin [32] have not proved satisfactory for steel refining.

§ 7. The Annealing, Hardening, and Tempering of Steel

Theories of heat treatment are really theories of the effect of time on the changes represented in terms of temperature and composition by the iron-carbon equilibrium diagram.—J. M. ROBERTSON.

In the mechanical working of steel ingots by rolling and forging, if the work is performed above the A_1-arrest it is called **hot-working.** The hot-working of steel, said A. Sauveur,[1] (i) closes blow-holes and promotes soundness; (ii) it at first increases the density by closing the blow-holes, and then decreases it; (iii) it destroys the pre-existing coarse crystallization, and produces a grain which when other things are equal is smaller the nearer the finishing temp. is to the critical range —hence the operation is known as the *mechanical refinement* of steel; (iv) it causes a deformation of the dendritic segregation, which results in a banded structure and directional properties; and (v) it at first increases tensile strength and ductility, both longitudinally and transversely, but on further refinement, while it may continue to increase the elongation and reduction of area longitudinally, it produces a decided decrease in those properties transversely. It also increases resistance to shock longitudinally, but decreases it transversely. These results are the more marked the more impure the steel or the more intense is its dendritic segregation— *vide infra,* heterogeneous alloys.

When the mechanical work—*e.g.* cold-drawings, rolling, or twisting—causing a permanent change of shape is performed below the A_1-arrest, the process is called **cold-working.** According to R. Job, A. Sauveur, and S. S. Martin, if the work is sufficiently vigorous to affect all parts of the mass, no crystallization takes place while the steel is being worked; and H. M. Howe found that hot-work has no direct action on the structure of the steel, but, as it retards crystallization until a lower temp. is reached, it may influence the structure in this way. According to A. Sauveur, the cold-working of steel (i) causes a permanent deformation of the components—ferrite, cementite, and pearlite—resulting in an increase in the hardness, tensile strength, and elastic limit, and a decrease in ductility; (ii) decreases the density, magnetic permeability, and remanence, and increases the coercive force; (iii) slightly increases the electrical resistance; and (iv) decreases the resistance to corrosion and to the action of acids. Cold-work distorts the grain, or flattens and elongates the crystals in the direction of rolling; and the lower the temp. the more pronounced the effects of cold-work. S. Sekito found the internal stresses in quenched steel due to the expansion of the lattice to be of the same order of magnitude as the tensile strength—*vide supra,* sp. gr.

Favre, E. W. Fell, C. F. Flolliott, A. Fry, R. L. Geruso, H. Giersberg, A. F. Golovin, G. W. Green, O. V. Greene, T. W. Greene, J. N. Greenwood, W. H. Hatfield, P. Heymans, E. Heyn, H. D. Hibbard, K. Honda and co-workers, B. Hopkinson, J. E. Howard, H. M. Howe and E. C. Goesbeck, S. L. Hoyt, J. C. W. Humfrey, T. M. Jasper, Z. Jeffries and R. S. Archer, J. D. Jevons, R. S. Johnston, J. A. Jones, W. Kerr, A. L. Kimball, F. Körber and E. Siebel, H. K. Landis, T. Leitner, P. Ludwik,

R. Mailänder, H. Malzacher, E. Marcotte, G. Masing, E. Maurer, E. Murata, A. Nadei and co-workers, A. Ono, B. Osann, A. J. S. Pippard and C. V. Miller, H. Poellein, E. P. Polushkin, A. Pomp and H. Poellein, A. M. Portevin, H. S. Rawdon, P. Régnauld, R. T. Rolfe, W. Rosenhain, P. A. Russell, G. Sachs, H. Scott, J. Seigle, S. Sekito, E. Siebel and A. Pomp, J. M. Snodgrass and F. H. Guldner, J. B. Sommerville, F. Stäblein, A. H. Stang and T. W. Greene, B. Strauss and A. Fry, W. Tafel, I. Takaba and K. Okuda, A. le Thomas, C. A. Trask, T. H. Turner and J. D. Jevons, A. W. Whitney, H. V. Wille, A. Wingham, and K. Yuasa studied the internal stresses in steel and iron.

T. Baker and T. F. Russell discussed the potential energy of cold-worked steel, and they assumed that the work done on the test-piece is $\int P.de$, where P denotes the applied load, and e the extension; and that the whole of that work is converted into heat excepting the quantity $\int\sigma(l+e)^{-1}de$, where σ denotes the load at the elastic limit; $(l+e)^{-1}$ denotes the area; and $\sigma(l+e)^{-1}$, the load. The subject was also discussed by G. M. Brown. T. F. Russell worked on the assumption that the increase in potential energy is accompanied by a change of phase—crystalline to amorphous or vitreous (q.v.). C. Barus calculated the energy potentialized in strained steel. If r_s and r_h denote the radii of wires before and after straining, P the stretching force, and $\delta l/l$ the longitudinal extension, then the work done per centimetre of length is $E=p\delta l/l$. If σ denotes the observed increment of temp., then E_θ/E will denote the part of the applied energy which is converted into heat, and the remainder $(E-E_\theta)/E$ represents the energy potentialized in virtue of the strain. For iron, $2r_s=0\cdot1362$; $2r_h=0\cdot1310$; $P=50,000$; $\delta l/l=0\cdot0875$; $P\delta l/l=4\cdot37$; $\theta=3\cdot9°$; and $E_\theta/E=0\cdot48$, so that 52 per cent. of the applied energy remains as potential energy. C. Barus was unable to detect any influence of mechanical strain on the state of the combined carbon in steel, but he did find that the rate of dissolution of steel wires hardened by drawing is greater than with the soft metal; and W. Rohn obtained a similar result. H. Hort estimated that the potential energy is of the order of 5 to 15 per cent. of the total work done on the test-piece. W. S. Farren and G. I. Taylor measured the energy stored in a metal during cold-working in terms of the difference between the heat evolved during deformation and the total work of deformation, and obtained 0·144 cal. per gram of metal with a 14 per cent. reduction; T. F. Russell obtained 2·27 cals. per gram. W. Spring made some estimates based on the difference of electrolytic potential of annealed and cold-worked metals. The subject was discussed by C. H. Desch, V. N. Krivobok, S. Sato, and T. Andrews—vide infra, electromotive force and tempering.

According to C. Barus, the density of white cast iron is of the order 7·6 and that of grey cast iron is 6·9; consequently, the density increases in a marked degree the greater the proportion of combined carbon in the metal. With steel the density decreases as the total carbon is more and more nearly combined, and the allotropic expansion produced by quenching steel is about 0·005. J. D. Everett found the vol. resilience of steel amounts to 2×10^{12}, so that if p be the value of the stress per sq. cm. for the given expansion, $p=10\times10^9$ dynes for steel. The tenacity of steel is 8×10^9 dynes per sq. cm., so that the approximate ratio of stress to tenacity is about 1·3 for steel; similarly, for glass the ratio is 3·3. In both cases stress is in excess. In the case of Rupert's drops it is probable that rupture would occur on quenching were it not for the favourable symmetrical structure of the globule. J. M. Batchelder observed that of twelve massive pieces of quenched steel, eight subsequently cracked, and one actually exploded—vide infra, sp. gr.

According to H. Wedding, the individual grains of malleable iron are ductile, and the malleability of the mass depends on the ductility of the separate grains. When press. is exerted on a single grain in the direction of one axis, as occurs, for example, when a piece of iron is hammered on an anvil, a scale is formed from the polyhedral grain. If, however, the press. acts in the direction of two axes, either at the same time, as in the case of rolling with a diagonal groove, or at different times, as in the case of hammering an ingot or rolling a bar, turning it round 90° after every passage through the rolls, the grain is converted into a column which is termed

a fibre. Sections cut parallel to the fibres when examined under the microscope
show a fibrous structure in which the separate fibres can be clearly followed, while
sections cut at right angles to the fibres show a granular structure. A fibre
cannot extend to any possible length without breaking up under the right con-
ditions into granules. If the carbon attains or exceeds 0·5 per cent., the fibres
split into grains with even a slight stretching. The same effect is produced with
a low percentage of carbon by a small proportion of phosphorus, a large amount of
silicon, or a moderate amount of sulphur.

Steels rich in carbon, and fine-grained iron usually form no fibres, but where
steel ingots, after solidification, are made up of closely interlocking dendrites
(Fig. 41), the dendritic segregation persists even when the dendrites have undergone
granulation on cooling. When such steels are forged or rolled, the portions rich
in the segregating elements or the fillings of the dendrites—*vide supra*—as well as
those poor in those elements—the axes—are elongated in the direction of the work.
Hot-worked steel thus acquires a laminated appearance (Figs. 42, 43, and 44), for
it seems to be composed of parallel bands. Figs. 41 to 44 are due to G. Charpy.
Figs. 41 to 44.—The Dendritic Structure of a Steel Ingot Before and After Cold-
Working.

Fig. 41 shows the dendritic structure of a steel ingot ; Fig. 42, the same after being
reduced to one-fifth of its original cross-section by hot-working ; Fig. 43, the same
after being reduced to one-thirtieth; and Fig. 44, after being reduced to a hundred-
and-fiftieth of its original cross-section. According to K. Nagasawa, the fibrous
structure in forged or rolled steels is a deformed structure of dendrite, in which the
segregation of impurities is present. Phosphorus is the impurity which chiefly
causes the fibrous structure. The fibrous structure is not completely removed by
an annealing below 1300°. The mechanical properties of forged or rolled steels
are superior in the direction of the fibres to what they are in the direction perpen-
dicular to them, and this directional difference is hardly reduced by a subsequent
heating below 1300°. The direction of the fibres has an intimate relation to the
lines of quenching cracks in steel.

M. Ettisch and co-workers observed that the crystallites in soft wires are
arranged irregularly, but in hard wires they are regularly arranged to give a fibrous
structure. E. H. Schulz and J. Goebel, and J. D. Gat studied the fibrous fracture
of steel ; C. O. Bannister, S. G. Smith, A. N. Farfourine, W. Rosenhain and
D. Hanson, F. Jansen, M. Hamasumi, K. Hübers, H. Pinsl, A. Wagner,
G. M. Enos, and F. Rogers, the fractures of iron and steel ; and J. Descolas and

E. Prétet, A. le Thomas, I. Iitaka, K. Nagasawa, W. Claus and R. Hensel, P. Oberhoffer and A. Heger, and M. Moreillon, the effect of mechanical treatment on the texture of iron and steel. G. Tammann and A. Heinzel, H. G. Keshian, B. Buffet and H. Thyssen, H. H. Meyer, A. Pomp and W. E. Schmid, A. Pomp and H. Poellein, P. Oberhoffer, W. F. Durfee, and F. Wever and E. Schmid studied the alterations in the orientation of the crystals produced by rolling ; E. F. Cone, G. Tammann and co-workers, T. M. Service, A. Campion, T. Matuschka, A. M. Portevin, F. C. Nix and E. Schmid, E. Schmid, F. Leitner, M. G. Yatsevitch, the structure acquired by casting ; E. Pitois, H. Wedding, and E. Schmid the texture of cold-worked metals ; and N. P. Goss, the X-radiograms of plastic deformation, when it was found that in the early stages of grain fragmentation there was no orientation of the crystal *débris* until the grains are all broken into particles of submicroscopic dimensions.

In the **heat treatment**—*Wärmebehandlung*—of iron and steel the attempt is made to impart certain desired physical properties to the metal through the agency of heat, chiefly by regulating the speed of cooling the metal in the austenitic condition so that it is converted into martensite, troostite, sorbite, or pearlite, or into aggregates of these constituents. The various forms in which the heat treatment is applied include annealing, normalizing, hardening, and tempering. In view of the predominant constituent present when particular qualities are desired, hardening can also be called *martensitizing* ; softening as *pearlitizing* ; and strengthening as *troostitizing* or *sorbitizing*. The structural changes due to cold-work can be altered by heat treatment up to or over the A_1-arrest. The process of **annealing**—*Glühen*—is often applied to counteract the hardening produced by cold-work, so as to make the metal soft and ductile by the release of internal strains and deformation produced by cold-work, the release of strains through the formation of pearlite, and grain refinement. In annealing, the metal is heated past its critical range so that on subsequent slow cooling it may be pearlitic and fine-grained. If the metal is heated below the critical range, no structural change occurs, except in the case of cold-worked hypo-eutectic steel, where distorted ferrite may assume its normal crystalline form. If the steel be heated to too high a temp., the structure of the metal may be coarsened— *vide supra*. The annealing temp. varies with the carbon content, since the position of the critical range, or rather its width, varies in the same way. The Heat Treatment Committee of the American Society for Testing Materials recommended 875° to 925° for steels with less than 0·12 per cent. carbon ; 840° to 870° for steels with 0·12 to 0·29 per cent. carbon ; 815° to 840° for steels with 0·30 to 0·49 per cent. carbon ; and 790° to 815° for steels with

Fig. 45.—Diagrammatic Representation of Heat Treatment Zone.

0·50 to 1·00 per cent. carbon. The results are summarized in Fig. 45. The object to be annealed must be kept in a given zone of temp. long enough to enable it to acquire that temp. in all its parts. Hypoeutectoidal steels suffer no change until the Ac_1-arrest is reached, when pearlite becomes austenite, and as the temp. rises the free ferrite is gradually absorbed and the iron is changed to γ-iron ; beyond the Ac_3-arrest the absorption of γ-iron is complete, and a homogeneous solid soln. of carbon or iron carbide in γ-iron is produced—to wit, austenite.

M. Brés, D. Ewen, P. Galy-Aché, P. Galy-Aché and M. Charbonnier, P. Goerens, L. Guillet, M. Hanriot, A. M. Portevin, F. Robin, A. Sauveur, A. Stadeler, H. P. Tiemann, J. F. Tinsley discussed the influence of annealing on the microstructure, and the persistency of the internal crystalline structure of steel which has been strained by local deformation. The annealing of steels was discussed by A. T. Adam, H. Brearley, A. Campion, H. Fay and S. Badlam, P. Goerens, N. P. Goss, R. Hohage and R. Rollett, H. M. Howe and A. G. Levy, R. Hugues, E. Marke, J. Muir, R. Schäfer, O. Sirovich, O. G. Styrie, C. D. Young and co-workers, and E. Zingg and co-workers, etc. ; and the annealing of malleable and cast iron, by H. Bornstein, W. Campbell, R. Carrick, P. Cheve-

nard and A. M. Portevin, F. B. Coyle, J. V. Emmons, E. Houdremont and co-workers, H. M. Howe and co-workers, O. F. Hudson, E. L. Leasman, E. E. Marbaker, J. E. Stead and A. W. Richards, and O. W. Storey.

According to Z. Jeffries, an austenitic steel with a coarse grain structure at atm. temp. and heated through the transformation temp. will have a larger austenitic grain than one with a smaller grain size. If the cooling is slow enough, these changes are reversed and the free ferrite may form distinct grains ; if the cooling is faster, the rejection of ferrite may be complete, but the time may be too short for the ferrite to collect in grains ; while if the cooling is still faster, only part of the liberated ferrite can be recognized ; while with a still faster cooling, only part of the rejected ferrite collects at the grain boundaries, and part remains as a kind of emulsion in the pearlite. Eutectoidal steels have only one critical temp., the $A_{3,2,1}$-arrest. Above that temp. austenite is formed, and below that temp. pearlite. Very slow cooling furnishes laminated pearlite, or the cementite may be more or less balled-up to furnish the structure known as divorced pearlite ; with faster cooling the pearlite laminations may be curly, or so fine as to be scarcely recognizable—the so-called granular pearlite—and with still faster cooling, the system seems emulsified, for no laminated structure or ferrite can be detected microscopically. This is the sorbite structure—or hardenite. The subject was discussed by J. O. Arnold. With hypereutectoidal steels—say, one with 1·20 per cent. carbon or 94·6 per cent. of pearlite and 5·4 per cent. excess cementite—cooling through the $A_{3,2,1}$-arrest gives laminated, granular, or divorced pearlite according to the rate of cooling ; the excess cementite is scarcely affected, since it was deposited above the zone of temp. now under discussion—*vide supra*. Consequently, the cooling should be slow if maximum softening and ductility are desired, since the steel then becomes pearlitic ; but if greater hardness, strength, and elasticity are desired, at the expense of some ductility, the cooling should be faster. As a rule, the lower the carbon content of the metal the more rapidly it may be cooled from the annealing temp. without seriously interfering with the ductility of the metal. H. C. Jones compared the effects of annealing in an atm. of nitrogen, or hydrocarbons, or in air.

The cooling of steel—*Normalglühen*—from the annealing temp. in air with the object of obtaining a uniform structure is usually called **normalizing** the steel. In normalizing, the steel is heated uniformly to a temp. exceeding its upper critical point, the Ac_3-arrest, by about 50°, and then cooled in air only ; but hypereutectoidal steels are heated high enough to break up and dissolve the brittle network and needles of cementite, and cooled fast enough to keep the excess cementite in soln. at atm. temp. The most favourable condition for producing uniformity in structure is to keep the solid metal at high temp. for a long enough time. In practice, however, such a treatment may modify the grain-size or crystalline structure so as to affect deleteriously the physical properties, and the steel may become one of the states previously described as over-heated or burnt. In any case, a considerable grain-growth may occur during the normalizing process, and the treatment also tends to equalize the grain-size. Hence, in order to produce a more or less homogeneous, soft, and ductile steel containing a minimum of hard and brittle cementite the normalizing must be followed by annealing just above the $Ac_{3,2,1}$-arrest, in order to produce a smaller grain-size and change hard sorbite or troostic sorbite into soft and more ductile pearlite. The annealing may be conducted very near to the $A_{3,2,1}$-arrest with the object of spheroidizing the steel, whereby the cementite is converted into rounded particles or spheroids instead of lamellæ as in ordinary annealing—*vide supra*. Spheroidizing usually follows the normalizing process. It increases the machining qualities and the toughness of steel, and makes it more amenable to hardening processes. The subject was discussed by W. Parker, E. Houdremont and H. Müller, S. Epstein and H. S. Rawdon, F. G. Sefing, C. H. Herty and co-workers, O. E. Harder and co-workers, R. Whitfield, B. M. Larsen and A. W. Sykes,

J. D. Gat, A. M. Portevin and P. Chevenard, O. Sirovich, A. Pomp, and W. E. Woodward.

According to E. W. Ehn,[2] a coarse-grained structure in the case or core of carburized steel with large crystals of pearlite, and clean-cut cementite at grain boundaries in network in the hypereutectoidal zone are signs of good or **normal steel**; while curly cementite, disintegrated pearlite in hypereutectoidal zone, and fine grained structure with rounded pearlite areas in the gradation zone and core of carburized steel are signs of an **abnormal steel**. In case-hardening, an abnormal steel has a tendency to give a thin case of high carbon-content and to form soft troostitic spots on hardening. The observations of H. W. McQuaid and E. W. Ehn, and of E. W. Ehn show that the abnormal structure is due to the presence in the steel of an excess of oxides, probably in the colloidal state. The particles of oxide act as centres of crystallization in the solidification of the steel. In normal steel comparatively few well-developed crystals are formed, while in an abnormal steel a large number of crystals interfere with the growth and development of one another. The original structure of solidification persists through the different stages of conversion and heat treatment. Hence, grain size with angular or triangular outlines of the pearlite is larger in normal steel than is the case with the more rounded areas of pearlite in abnormal steels. The particles of oxide retain their mutual position in the steel, and later on arrange the crystals in accord with this outline during the secondary crystallization of the steel. Observations were made by J. D. Gat, and S. Epstein and H. S. Rawdon. According to O. E. Harder and co-workers, the lattice dimensions of abnormal steel are greater than those of normal steels, indicating the presence of foreign material, probably oxide, in solid soln. in the ferrite—otherwise expressed, the oxygen goes into the space-lattice of the iron, and there exercises some bonding valencies with the adjacent iron atoms. Heating abnormal steel at the carburizing temp. in vacuo had no effect on the normality; heating normal steel in nitrogen at about 940° did not change its carburizing qualities—presumably because nitrides are not formed at this temp.; heating normal steel in oxygen at about 940° produced an abnormal steel—presumably owing to the formation and dissolution of oxides in the steel; and heating normal steel in carbon dioxide at about 940° produced abnormal steel—presumably owing to the oxidizing action of the gas. When normal steel is heated in contact with various oxides at the carburizing temp., abnormal steels are produced by the dissolution of oxides. The depth of penetration of the oxides is proportional to the time of heating. Of the various oxides tried—Fe_3O_4, Fe_2O_3, Al_2O_3, and slag—ferric oxide penetrates the most rapidly and produces the most abnormal steel for a given time of heating. The rate of penetration of the oxide or oxygen, as determined by the formation of an abnormal carburizing zone, is exceedingly slow as compared with carbon penetration. The carbon is able to penetrate through a surface of abnormal steel and then produce a normal hypereutectoid zone. The more rapid penetration of the carbon, as compared with that of the oxygen, is probably attributable mostly to the relative affinities of oxygen and carbon for iron—or to state the same relation in another way, the relative stabilities of iron carbide and iron oxide compounds. In addition, the carbon atom is smaller than the oxygen atom and should for that reason diffuse more rapidly. Melting abnormal steel in vacuo in alundum or magnesite crucibles decreased the abnormality, and a normal steel under similar conditions became more or less abnormal. Melting normal steel in an alundum crucible in nitrogen or carbon monoxide produced more or less abnormality.

It is often said that civilization, directly or indirectly, owes to **the hardening properties** of steel very many advances which have been made. The hardening—*Härten*—of steel is effected by heating the metal above its critical temp., say to bright redness, and cooling relatively quickly, say by **quenching**—*Abschrecken*—it in a relatively cold liquid or in air. This fact has been known and utilized for ages. H. C. H. Carpenter and J. M. Robertson [3] observed that samples of ancient implements dating from about 1200 B.C. showed that the Egyptians were acquainted with the hardening, carburizing, and heat treatment of iron; and N. T. Belaiew considered that the evidence showed that the Egyptians learned the art after the battle of Kadesh, when they came into contact with the Hittites and other peoples of Asia; and that the art probably originated in Asia Minor, possibly Anatolia—*vide supra*, the history of iron. According to F. M. Feldhaus, St. J. V. Day, P. Jordan, O. Vogel, L. Beck, and B. Neumann, the Greeks knew at an early date that iron could be hardened by quenching the hot metal in water or in oil. Thus Homer, in his *Odyssey* (**9.** 93), related that when Ulysses plunged a stake into Cyclop's eye, the tumult was like that produced

> When the armourer tempers in the ford
> The keen-edged pole-axe, or the shining sword,
> The red-hot metal hisses in the lake.

It is said that the Chinese *Shoo King*, 2500 B.C., mentioned hardened iron. In Sophocles' *Ajax* (720) there is a comparison of being hardened like immersed iron ; Lucretius, in his *De rerum natura* (**6.** 148), may possibly have had in mind the hardening of steel by quenching. M. Lister discussed the passages bearing on this subject in Aristotle's Μετεωρολογικά (**4.** 6), and in Pliny's *Historia naturalis* (**34.** 14). According to H. Hanemann, a metallographic examination of some Celtic implements from Steinsburg, Thuringia, showed that the art of hardening steel was practised in Thuringia before the Germans settled there ; B. Neumann likewise examined some specimens, dating from the beginning of this era, and inferred that the carburization of iron was known in 200 A.D., but the specimens gave no evidence of quenching. In 1689, C. Salmasius described the process used for hardening iron in India. In the first century of our era, Pliny, in his *Historia naturalis* (**34.** 14 ; **39.** 41), said that :

There is a very great difference when glowing iron is immersed in water. . . . It is used to quench thin pieces of iron in oil, for water would make them so hard as to be brittle. . . . The main difference in the steel prepared in different places results from the quality of the water into which the red-hot metal is plunged. The water is in some places—*r.g.* Bilbilis (Bambola near Calatayud), Tariasso (Tarragona), and Comum in Italy—better for this purpose than in others, and consequently some localities have become quite celebrated for the excellence of their steel even though no iron mines occur in these localities.

In consequence, attention was focused on the liquid employed for quenching ; it was believed that something passed from the liquid into the steel ; and some curious solutions and fantastic nostrums were recommended for this purpose during the period extending up to the sixteenth century, and even up to the present day. In the Middle Ages Justin, in his *Historiæ Philippicæ* (**44.** 4), referred to the subject ; and the hardening of steel was discussed by J. J. Becker, J. le Bègue, M. Eraclius, J. R. Glauber, R. A. F. de Réaumur, J. J. Wecker, etc. Even as late as 1810, in an anonymous book of trade secrets, it is said that steel will be hardened if quenched in an infusion of the roots of blue lilies or in urine ; and it will become as soft as lead if quenched in a decoction of common beans. The subject was discussed by B. Neumann, E. Grateau, etc. M. von Eulenspiegel found the remains of the workshop of an ancient armourer amongst the ruins of ancient Tyre. The " find " included a parchment describing in Syriac characters the hardening of Damascus sword blades. He thus translates :

Let the high dignitary furnish an Ethiopian of fair frame, and let him be bound down, shoulders upward, upon the block of the God Bal-hal, his arms fastened underneath with thongs ; a strap of goatskin over his back, and wound twice round the block ; his feet close together lashed to a dowel of wood, and his head and neck projecting over and beyond the ond of the block. . . . Then let the master workman, having cold-hammered the blade to a smooth and thin edge, thrust it into the fire of the cedarwood charcoal, in and out, the while reciting the prayer to the God Bal-hal, until the steel be of the colour of the red of the rising sun when he comes up over the desert toward the East, and then with a quick motion pass the same from the heel thereof to the point, six times through the most fleshy portion of the slave's back and thighs, when it shall have become the colour of the purple of the king. Then, if with one swing and one stroke of the right arm of the master workman it severs the head of the slave from his body, and display not nick nor crack along the edge, and the blade may be bent round about the body of a man and break not, it shall be accepted as a perfect weapon, sacred to the service of the God Bal-hal, and the owner thereof may thrust it into a scabbard of asses' skin, brazen with brass, and hung to a girdle of camel's wool dyed in royal purple.

R. Theophilus towards the end of the eleventh century said that in order to harden tools for cutting glass and stone a he-goat, three years old, should be made to starve for three days, and then nourished with fern for two days, during which time the urine should be collected and used for hardening tools. He also said that the urine from a red-haired boy exerts a stronger action than does ordinary water. In the sixteenth century H. Cardanus said :

Steel is nobler than iron ; the best is that with small white cores. . . . If it is well cleaned, and then, while red-hot, quenched three or four times in a mixture of radish juice and water from earthworms, it will cut iron as if it were lead.

J. Ferguson pointed out that a sixteenth-century anonymous book on trade secrets advocated that the right use of alchemy is to apply chemical knowledge to industry, and the following quaint recipes were given for hardening steel :

Take snayles and first drawn water of a red die of which water being taken in the two first months of harvest when it raynes, boil it with the snayles, then heate your iron red hot, and quench it therein, and it shall be hard as steele. . . . Ye may do the like with the blood of a man of XXX years of age and of a sanquine complexion, being of a merry nature and pleasant, distilled in the middst of May.

The old workers, after all, may not have been so very far from the truth in assuming that special virtues resided in the liquid employed for quenching, since J. A. Brinell found the hardness of a steel with 0·45 per cent. C ; 0·27, Si ; 0·45, Mn ; 0·018, S ; and 0·028, P, which before hardening had a Brinell's hardness of 202 after quenching from 780°, had a Brinell's hardness of 217 using boiling water as the quenching liquid ; 223, using bitter milk at 20° to 25° ; 235, using wood-tar at 80° ; 241, using lead at 360° ; 248, using petroleum at 20° to 25° ; 255, using tallow at 80° ; 293, using skimmed milk at 20° to 25° ; 302, using sweet milk at 20° to 25° ; 402, using sulphuric acid, sp. gr. 1·837, at 20° to 25° ; 555, using whey at 20° to 25° ; 600, using soapy water (1 : 10) at 20° to 25° ; 627, using a sat. soln. of sodium chloride at 20° to 25° ; and 652, using soda-water at 20° to 25°. K. Honda and K. Iwase stated that the fact observed by J. A. Mathews that, in the case of alloy steels, more austenite is produced by oil-quenching than by water-quenching is valid only for thick plates or rods in which the internal stress caused by rapid cooling is fairly large and can be explained as an effect of stress—*vide supra*, martensite.

When steel is hardened, it is first heated above the A_1-arrest, Fig. 46, and then more or less abruptly cooled. Very little, if any, increase in hardness occurs if the steel be heated to a temp. lower than the critical range. This means that before quenching the metal must be in the condition of a solid soln. of iron and carbon or iron carbide, because the aggregate of ferrite and cementite formed on slow cooling through the critical range cannot be hardened by quenching. If the temp. be too high, the structure is coarsened without materially increasing its hardening power ; and quenching from too high a temp. increases the risk of warping and cracking the objects in the quenching. To produce the maximum hardness combined with the finest possible texture the metal should be heated just beyond the critical range, and cooled as soon as it emerges from the critical range of temp. Abrupt cooling or quenching arrests the change of martensite into soft pearlite ; so that quenching more or less fixes the constitution the steel possessed just before quenching. Quenching arrests the transformation of austenite into pearlite at the martensite stage. H. C. Boynton found the hardness of the different stages in the transformation to be as follows (ferrite unity) :

$$\text{Austenite} \rightarrow \text{Martensite} \rightarrow \text{Troostite} \rightarrow \text{Sorbite} \rightarrow \text{Pearlite}$$
$$104\text{·}0 \qquad 239\text{·}0 \qquad 88\text{·}0 \qquad 52\text{·}0 \qquad 4\text{·}3$$

Rapid cooling hardens steel, provided the operation starts above the transformation range, but not if it starts below that range. If the cooling starts within the transformation range, the metal is hardened to an intermediate degree, dependent on the state of the metal. In any case, the proportion of martensite which escapes transformation into pearlite determines the hardness. The hardness of martensite increases with the carbon content. Other things being equal, J. O. Arnold showed that it does not matter much at what temp. the cooling begins, provided it is above the critical range, 720°. The heating of the steel should be slow enough to permit it gradually and evenly to acquire a uniform temp. C. Benedicks, and J. A. Mathews found that a higher initial temp. produces a quicker rate of cooling than a lower temp., so that large pieces, in general, are heated to a higher temp. than smaller pieces. A. M. Portevin emphasized the fact that the dissolution of cementite in the hardening process requires time, and that the objects should be

heated at the hardening temp. until all is transformed into austenite. The zone or range of the critical temp. varies with different steels ; medium and low carbon steels require a higher quenching temp. than high carbon steels, because in order to acquire dull hardening power they must be heated past their Ac_3- or $Ac_{3,2}$-arrests as the case may be. The increase in hardness produced by quenching is greatest with eutectoidal steel ; actually, quenched hypereutectoidal steels are harder than quenched eutectoidal steels because of the presence in the former of free cementite or carburized martensite. The general behaviour of steel during cooling and quenching was studied by G. V. Luerssen, W. F. Chubb, H. J. French, F. Wever, and A. M. Portevin. H. le Chatelier thus summarized the effects of cooling on 0·8 per cent. carbon steel initially in the austenite stage :

Rate of cooling			Transformation	Final State
Slow	.	.	Austenite→pearlite	Pearlite
Medium	.	.	Austenite→martensite→pearlite	Troostite
Rapid	.	.	Austenite→martensite	Martensite
Very rapid	.		None	Austenite

F. Osmond, L. Demozay, P. Chevenard, P. Dejean, J. E. Hurst, H. le Chatelier, A. Lundgren, B. Strauss, and A. M. Portevin and M. Garvin have also shown that increasing the speed of cooling from above the critical range lowers the Ar_1-arrest ; this lowering is at first gradual, but becomes quite sudden for a certain cooling
FIG. 46.—The Effect of the Speed of Cooling on the Ar_1-Critical Point, and the Microstructure.

velocity—the critical speed of quenching, or the critical rate of cooling. The observations are summarized diagrammatically in Fig. 46. With a sufficiently slow rate of cooling the Ar_1-transformation occurs at about 700°, and austenite is transformed into pearlite ; by increasing the rate of cooling the transformation temp. is lowered and the steel becomes sorbitic ; as the rate of cooling increases the transformation temp. is depressed to about 650°, and troostite appears ; and at a slightly greater speed of cooling a second arrest abruptly appears at a much lower temp., and martensite appears ; while with a still

faster rate of cooling the upper Ar_1-arrest disappears, and the lower Ar_1''-arrest alone appears. When austenite is transformed at about 300°, martensite is formed. The appearance of the Ar_1''-arrest occurs at the so-called critical speed of quenching. If the transformation could be delayed by rapid enough cooling to ordinary temp., the steel would remain austenitic. This has been realized with manganese and nickel steels. A. M. Portevin found that when the cooling is fast enough to cause the transformation to occur at 300°, the hardening is only superficial—about 5 to 6 mms. thick ; and generally the greater the speed of cooling required to attain the critical speed, the more superficial the hardening. The intensity of the Ar_1'-arrest decreases as the temp. falls from T_1 to T_2, and at the same time the intensity of the Ar_1''-arrest increases as the temp. is lowered from T_3 to T_4. At the Ar_1'-arrest troostite seems to form around the corners of the austenite grains, and the central portions of the grains pass into martensite at the Ar_1''-arrest. K. Honda found that the doubling of the arrest can be studied better with nickel steels—vide infra, manganese steels, Fig. 46 ; vide supra, the doubling of the Ar_1-arrest. K. Honda and T. Murakami called the Ar_1'- and the Ar_1''-arrests a *stepped Ar_1-transformation—vide supra*. H. Scott inferred that the Ar'-arrest involves the transformations $Ar_{3,2,1}$, and the Ar''-arrest the transformations $Ar_{3,2}$. The transformation Ar_2 is suppressed when Ar'' is observed, and it appears on a heating curve as an evolution of heat, and it is accompanied by the formation of troostite

or a coarser condition of carbide. The maximum of the transformation $Ar_{1,2,3}$ occurs at a higher temp. when the previous cooling gives Ar′ rather than when it gives Ar″. The subject was discussed by T. Murakami, T. Matsushita, T. Sutoki, P. Longmuir, H. de Nolly and co-workers, S. V. Bielznsky, H. Scott, etc.

H. Caron, and E. Hitzel discussed the quenching of steel in hot water. Observations on the effect of the rate of cooling, and on the cooling power of different liquids for quenching were made by J. A. Brinell, S. Haedicke, E. Jarolimek, L. Demozay, N. B. Pilling and T. D. Lynch, G. W. Pressell, P. Chevenard, H. V. Wille, C. D. Young, W. J. Merton, V. E. Hillman, J. Hébert, H. J. French and T. E. Hamill, R. Kühnel, C. Benedicks, J. Mercier and P. Michoulier, H. J. French and co-workers, E. Hitzel, D. Hattori, A. McCance, L. Grenet, J. A. Mathews and H. J. Stagg, S. E. Derby, J. B. Morey, W. G. Lottes, O. Smalley, A. M. Portevin, P. J. Haler, A. Mumper, R. M. Sandberg, B. H. de Long and F. R. Palmer, F. L. Wright, and K. Honda and K. Tamaru, J. H. Andrew, L. Roy, I. Obinata, H. Haedicke, E. Blass, P. Lejeune, W. J. Crook and co-workers, D. Uno, T. E. Hamill, F. B. Coyle, and J. Seigle; and H. le Chatelier, and J. A. Mathews found that (i) the rate of cooling in water remains constant up to a temp. of 37°; (ii) soln. of brine produce a faster rate of cooling, and retain their cooling power unimpaired so long as their temp. remains below 65°; and (iii) while oil-baths produce a slower rate of cooling, they can be heated to a much higher temp. without affecting seriously their cooling power. L. B. G. de Morveau mentioned the use of a water spray. R. A. F. de Réaumur used solid tin and solid lead as cooling agents; and also mercury; T. Gill, E. Lisbonne, and A. Evrard studied the use of lead baths; and L. A. Levat, phenol. C. Benedicks, and H. le Chatelier found that mercury is inferior to water; while C. Benedicks found methyl alcohol is superior to water as a cooling liquid. H. Scott, and G. Feodoséeff tried glycerol. C. Benedicks showed that the quenching power of a liquid depends largely on the latent heat of vaporization, and not on the initial temp. of the liquid or on its heat conductivity. H. le Chatelier also showed that sp. ht. rather than heat conductivity governs the speed of cooling. Mercury with a heat conductivity over ten times that of water is less effective as a cooling medium. A. M. Portevin and M. Garvin said that the rate of cooling is affected by (i) the temp. of the sample to be quenched; (ii) the mass form and dimensions of the sample; (iii) the position of a given point in the interior of the sample; (iv) the nature of the quenching bath, for the effect depends on the sp. ht., thermal conductivity, viscosity, and latent heat of vaporization of the medium; (v) the temp. of the bath, which may vary during the process of cooling; (vi) the agitation of the quenching liquid; (vii) the state of the surface of the sample; and (viii) the temp. of the liquid at the end of the cooling.

Hardened carbon steel contracts when it is kept for some time, and the process is accompanied by an evolution of heat. C. F. Brush and co-workers attributed the effects to the gradual relief of the strains produced during quenching—*vide supra*, martensite. The dilation of steel during quenching was studied by G. M. Eaton; the distribution of austenite in steel during quenching, by K. Honda and A. Osawa; C. Benedicks also showed that a certain amount of austenite is transformed into martensite at ordinary temp., but the transformation is opposed by the press. induced by the higher sp. vol. of the martensite. The separation of hard cementite is attended by a decrease in vol., and the transformation of γ- to α-iron, by an increase in vol. According to C. Benedicks, and Z. Jeffries and R. S. Archer, the separation of finely-divided cementite explains the tendency for a quenched steel to assume a greater hardness by ageing, even at ordinary temp. The subject was studied by C. E. Stromeyer, G. Sachs and W. Stenzel, R. F. Mehl, W. Köster, H. Lent and F. Kofler, G. Masing, L. B. Pfeil, F. Körber and A. Dreyer, W. P. Wood, W. P. Sykes and Z. Jeffries, J. Galibourg, A. Pomp, F. Nehl, O. Bauer, E. Murata, F. S. Merrills, F. Sauerwald, A. Krüger, F. R. Hensel, A. Sauveur

K. Aders, W. Guertler, G. Sachs, P. Chevenard and A. M. Portevin, C. G. Heiby and G. Coles, L. C. Brant, W. H. Hatfield, H. J. French, H. Scott, B. F. Sheperd, G. V. Luerssen, G. Masing, W. Rosenhain, A. Michel and P. Benazet, H. Jungblüth, A. L. Bates, H. von Kroeckritz, J. Seigle, E. W. Ehn, S. S. Steinberg and W. Suboff, M. L. V. Gayler, F. Fettweis, K. Honda and S. Idei, G. A. Reinhardt and H. L. Cutter, and O. E. Harder and R. L. Dowdell. The spontaneous evolution of heat by hardened steel was noticed by C. F. Brush and co-workers. F. Cloup noted that the heating curves of quenched or cold-worked steels show evolution of heat at about 400°; the change is irreversible, and the cooling curves show no such phenomenon. K. Tamaru found that the density of steel consisting of β-martensite, at 200°, is less than that of annealed steel, but greater than that of quenched steel. T. Matsushita concluded that in the **seasoning or ageing of steel**: (i) Steels which are imperfectly hardened always exhibit a gradual elongation, or an elongation associated with a subsequent contraction. (ii) In steels which are well-hardened there is always a gradual contraction. (iii) The elongation is explained by the incomplete Ar_1-transformation, while the contraction is due to separation of unstable cementite from its solid soln.—the martensite. (iv) The complete separation of the first unstable cementite at room temp. requires several months or over one year, but by heating the steel to about 100° the same separation follows within two hours. (v) The separation of the unstable cementite does not affect the hardness of the steel appreciably, but the separation of the more stable cementite is associated with a loss of hardness. (vi) The electric resistance of a steel considerably increases by quenching, and decreases by tempering; this increase is due to the cementite in solid soln. (vii) The gradual elongation or contraction of quenched steel is always accompanied by an evolution of heat. This heat is the heat of transformation, but is not caused by yielding strain, as was generally supposed to be the case. P. Chevenard and A. M. Portevin studied the changes in the composition of the cementite during the ageing of the austenitic steels, by measuring the thermal expansion, hardness, electrical resistance, and remanent magnetism. Below 200° a carbide with a Curie point of 120° is precipitated and the iron returns from the γ- to the α-state at 200° to 225°, when another carbide with a Curie point of 170° is precipitated. Above 260° the transformation of the austenite to martensite and a carbide occurs, and the proportion of carbide becomes progressively less as the temp. rises. At 400° the steel is completely in the form of sorbite, and at higher temp., the precipitated carbide becomes richer in manganese at the expense of the ferrite. Observations were also made by M. Sauvageot; and W. Fraenkel and E. Heymann studied the kinetics of the operations—*vide supra*.

The early workers made several guesses in their attempt to explain how steel is hardened by quenching. According to E. Wiedemann, the Arabian Al Kâli early in the eleventh century said that iron exists in two forms, male and female; soft iron is the female, steel the male variety. In the thirteenth century Albertus Magnus said that water, the principle of fusibility, occurs in iron and gives it a certain softness, and if iron be made glowing hot, this most subtle, aqueous part distils away, and the remainder, in consequence, is hardened. Thomas Aquinas, A. Barba, and Basil Valentine held similar opinions. Robert Boyle, J. Locke, Isaac Newton, P. von Muschenbroek, and W. Nicholson referred hardness to the cohesion of the constituent particles. T. Hobbes, R. A. F. de Réaumur, and G. Agricola discussed the subject. O. Tachen said that when steel is quenched in water it acquires strength because " the light alcaly in the water is a true comforter of the light acid in the iron, and cutlers do strengthen it with the alcaly of animals "; and N. Lemery also mentioned that steel is produced by heating iron in the presence of horns of animals. G. Agricola, in 1546, seems to have regarded steel as purified iron—*ferrum sæpius liquefactum et a recrementis purgatum*; A. Libavius, in 1606, compared the production of steel from iron with that of cement copper by iron; and, in 1779, J. Demeste regarded steel as iron free from what

was then called zinc. G. E. Stahl said 'that steel is merely iron possessing, in virtue of its phlogiston, the characteristics of a metal in a higher degree than iron. A similar idea appeared in the works of J. F. Henkel, K. Neumann, J. A. Cramer, C. E. Gellert, S. Rinman, R. Kirwan, and P. J. Macquer. T. Bergman also held the phlogiston theory with respect to steel, although by oxidizing wrought iron, steel, and cast iron he showed that the percentage amounts of carbon in these materials were respectively 0·05 to 0·20, 0·20 to 0·80, and 1·00 to 3·00. J. Black attributed the hardness of steel to the extrication of latent heat ; and the abatement of the hardness by temper, to the restoration of a part of that heat. The observations of L. B. G. de Morveau, in 1786, and of J. R. Bréant, in 1823, have been previously discussed. R. A. F. de Réaumur experimented on the subject and concluded that " since the hardening of steel is due neither to the intervention of a new substance, nor to the expulsion of air, it remains to seek its cause in the changes occurring in its substance." When steel is heated, the " sulphurs and salts " are driven from the molecules into the interstitial spaces ; when the metal is abruptly quenched, the " sulphurs and salts " have not time to return to the molecules, but remain firmly cemented in the interstitial spaces, and hard, rigid steel is formed. In tempering, the " sulphurs and salts " partially return to the molecules, and the metal becomes proportionally soft.

The hardening, annealing, and tempering of steel, etc., are described in many textbooks and the general subject was discussed by R. R. Abbott, A. T. Adam, J. Adamson, J. H. Andrew, W. R. Angell, H. H. Ashdown, E. C. Bain and W. S. N. Waring, J. H. Baker, O. Bauer, O. M. Becker, A. E. Bellis, C. M. Bigger, H. Birnbaum, J. W. Bolton, H. M. Boylston, S. N. Brayshaw, H. Brearley, H. Busch, E. D. Campbell, W. Campbell, A. Campion, F. Camus, G. Charpy, P. Chevenard, E. F. Cone, J. Cournot, W. J. Crook, J. J. Curran, H. Damemme, E. F. Davis, G. Delbart, C. H. Desch, J. Durand, G. M. Eaton, G. Ede, B. Egeberg, W. Eilender, H. Esser and W. Eilender, E. W. Esslinger, G. S. Evans, H. Fay, R. B. Fehr, G. Franche, H. J. French, L. H. Fry, C. H. Fulton and co-workers, L. de Gerando, R. L. Geruso, F. Giolitti, N. P. Goss, L. Grenet, E. Greulich, M. A. Grossmann, L. Guillet and co-workers, P. J. Haler, J. H. Hall, H. Hanemann and co-workers, J. F. Harper and R. S. MacPherran, J. W. Harsche, D. Hattori, R. Hay and R. Higgins, R. A. Hayward, W. Heike and W. Brenscheidt, A. Heller, C. T. Hewitt, E. Heyn, E. Heyn and O. Bauer, H. D. Hibbard, O. Hoffmann, K. Honda, K. Honda and A. Osawa, H. M. Howe and A. G. Levy, W. P. Ishewsky, C. M. Johnson, B. E. Jones, A. Jung, H. Kalpers, M. Kawakami, H. C. Knerr, H. B. Knowlton, F. Körber. W. Köster, J. B. Kommers, E. F. Lake, F. C. A. H. Lantsberry, E. L. Leasman, P. Lejeune, P. Longmuir, H. Lüpfert, G. V. Luerssen, J. Lund, D. J. McAdam, A. McCance, G. W. McKee, P. E. McKinney, E. E. Marbaker, E. Marke, E. R. Markham, J. A. Mathews and H. J. Stagg, T. Matsushita and K. Nagasawa, E. Maurer, A. Merz and C. Pfannenschmidt, A. Michel and P. Bénazet, E. C. Miller, E. Müncker, P. Murnoch, O. Oberhoffer and co-workers, F. Osmond, C. Otto, E. Piwowarsky, C. H. Plant, A. Pomp, A. M. Portevin and co-workers, A. Poucholle, F. Rapatz and H. Pollack, F. Reiser, R. Rimbach, W. C. Roberts-Austen, J. M. Robertson, F. Robin and P. Gartner, P. Rohland, E. Ryd, G. Sachs, S. Sato, M. Sauvageot and H. Delmas, A. Schack, A. Schleicher, E. Schüz, H. Scott, R. M. Sherry, F. T. Sisco, E. K. Smith, J. E. Stead, S. S. Steinberg, B. Stoughton, C. E. Stromeyer, H. Styrie, K. Tamaru, O. Thallner, C. Tronson du Coudray, D. K. Tschernoff, J. W. Urquhart, A. Vierendeel, C. M. Walter, A. Weber, H. Wedding, O. Wedemeyer, M. Weidig, F. Wever, J. H. Whiteley, S. G. Williams, J. K. Wood, W. P. Wood, J. V. Woodworth, F. Wrightson, and J. B. Zabé.

The phlogiston theory of the nature of steel was rejected by C. A. Vandermonde, C. L. Berthollet, and G. Mongé, who, in their *Mémoire sur le fer considéré dans ses différents états métalliques*, in agreement with T. Bergman, showed that the difference in the main varieties of iron is determined by variations in the proportions of carbon, and that steel must possess a definite proportion of carbon in order that it may possess definite qualities. This factor in *l'aciération* was confirmed by the experiments of L. Clouet, F. Margueritte, W. H. Pepys, and others indicated in connection with the iron carbides—**5.** 39, 20. Near the middle of the eighteenth century C. Linnæus, in his *Pluto Svecicus*, said that steel is devoid of sulphur, meaning by " sulphur " an inflammable substance (phlogiston) ; and another school regarded steel as iron containing an inflammable substance. These divergent views are accounted for by the approach to the metal being made in different ways.

In one case attention was concentrated on the extraction of iron from its ores, and in the other on the production of steel by cementation. The correct view, said C. Benedicks, was set forth in the anonymous French work *Traité sur l'acier d'Alsace, ou l'art de convertir le fer du fonte en acier*, published at Strasburg in 1737, probably by the brother of G. Bazin.

It is generally agreed that the hardening of steel by rapid cooling consists essentially in the martensitization of the metal through the suppression of the transformations which austenite normally undergoes when it changes into pearlite. The transformation is suspended while the alloy is in the form of hard martensite. It is, indeed, an example of an arrested reaction—**4.** 31, 20. The martensite, so to speak, is trapped by the abrupt cooling. If some austenite has escaped transformation, it will not be so hard as if it had been completely martensitized, because austenite is softer than martensite; similarly, if some martensite has passed into the pearlite stage, the product is still softer. In fine, the degree of hardness of a steel quenched from above the transformation range is roughly a measure of the proportion of metal caught in transit in the martensite stage. The transformation of the martensite at ordinary temp., under ordinary conditions, is too slow to be of any consequence. According to H. M. Howe and co-workers, the suppression of the transformation of austenite before it passes beyond the martensite stage, that is, martensitization, is produced by (i) cooling carbon steels rapidly from the austenite stage; (ii) by the addition of a small proportion of an element, like nickel or manganese, which introduces a kind of lag, hysteresis, or passive resistance, hindering or obstructing the transformation beyond the martensite stage; (iii) by the super-cooling of cold austenitic steel in, say, liquid air; (iv) by overstraining austenitic steel by cold deformation, for this enables the austenite to pass into hard martensite; (v) by a reheating of austenitic steels to such a temp. that the austenite can pass into martensite; and (vi) by subjecting the metal to plastic deformation—*vide infra*, hardness.

Hardness in a general way may be regarded as a resistance offered to permanent deformation. Metals owe their resistance to deformation to attractive and repulsive forces between the atoms. A permanent deformation, therefore, involves changes in the relative positions of some of the atoms and the rupture of some interatomic bonds. Rupture takes place by degrees—*vide supra*, slip bands—so that the breaking of the atomic bonds does not proceed simultaneously. The different hypotheses which have been suggested are not necessarily mutually exclusive.

In one group of hypotheses the hardness of the martensite is referred to some peculiarity of the iron—say β-iron. This means that the cohesive forces of the atoms of this allotrope are assumed to offer a greater resistance to deformation than do the cohesive forces of the other allotropic forms of iron. In the so-called **allotropic iron theories of hardening**, expounded by F. Osmond,[4] and mainly of historical interest, it is supposed that hardened steel consists of a soln. of iron carbide or carbon in β-iron. The mixture is supposed to contain some α-iron in order to account for the magnetic properties. F. Osmond said :

Hardened steel is a steel in which the iron and carbon have preserved more or less completely in the cold the condition which it possessed at high temp. The heat of the change that has not been affected remains disposable in the metal, and may be termed the latent heat of hardening. We conclude that hardened steel owes its properties principally to the presence of β-iron, which is hard and brittle by itself at the ordinary temp. Carbon in the state of hardening carbon maintains iron in the condition during slow cooling up to a temp. which is in inverse proportion to the amount of carbon contained in the metal. . . . The influence of carbon is of the same character as that of the rate of cooling, and both combine to produce the final result. The rate of cooling alone is not sufficient under ordinary conditions in which hardening is effected to maintain an appreciable fraction of the iron in the β-condition. But as, under the same conditions, it is easy to maintain the carbon in the state of hardening carbon, and as the hardening carbon imparts stability to β-iron, it is evident in what manner β-iron may be successfully preserved up to the ordinary temp. by the aid of carbon. The more rapid the cooling, the more incomplete are the changes and the harder is the hardened metal.

⁓ The β-iron hypothesis has been previously discussed, and the β-iron hypothesis of hardening is dependent on the assumed properties of that allotrope. The equilibrium diagram shows that steels with up to 0·45 per cent. of carbon when quenched from between 900° and 750° would consist of β-iron and γ-solid soln.; while steels with up to 0·85 per cent. of carbon quenched from between 750° and 700° consist of α-iron and γ-solid soln. Consequently, C. A. Edwards said that β-iron does not enter into the constitution of steels containing more than 0·45 per cent. of carbon. H. le Chatelier, and L. Guillet deny the existence of β-iron, and hold that the A₂-arrest does not represent an allotropic change. They also believe that the soln. is that of a carbide in α-iron, and that the hardness is due to the internal pressure caused (i) by the contraction of the red-hot material, and (ii) by the change in volume which attends the partial or complete change of austenite to martensite. Instead of β-iron, it has also been assumed that the iron of martensite is a soln. of γ-iron in α-iron. Indeed, all the possible changes have been rung in attempting to explain the hardness of martensite by assuming that it is due to the condition of the iron—α-, β-, or γ-iron and the possible combinations of these. As a result, C. A. Edwards could say that it is legitimate to infer that none of these allotropic forms of iron, as such, is an adequate cause of the hardening of carbon steels quenched from above the critical points. The subject was discussed by E. Maurer—*vide supra*, the allotropes of iron. G. Sirovich and R. Ariano invented another form of α-iron to explain hardness. G. Charpy said that the hardening produced in the cold metal by a permanent deformation by strain and that produced by quenching from a high temp. are similar states.

G. T. Beilby's theory of amorphous iron (*q.v.*) previously discussed has been adapted to explain the hardness of steel—the **amorphous state theories of hardening.** The hard structure is supposed to be due to the formation of an amorphous soln. of carbide in α-iron during the change from one allotropic form to another. The sudden lowering of the temp. prevents the viscous mass from crystallizing in a new state, so that the metastable, amorphous state is retained in the cold. This hypothesis was advocated by J. C. W. Humfrey. The interstratal movements caused by the dilation which accompanies the γ-iron→α-iron or the austenite→pearlite transformation are supposed to break up the crystalline condition of the iron and make it amorphous, and if the cooling is fast enough, this iron does not crystallize, but is trapped, so to speak, while it is in the hard and amorphous state. W. E. Williams found that the X-radiograms of hardened steel agree with the assumption that the hardness of martensite is due to the presence of amorphous material which crystallizes out in the tempering process. W. Rosenhain supposed that the amorphous iron is formed during the rapid cooling from a state in which every grain is encased in a thin, amorphous envelope; in cooling there is not enough time for the growth of the grains of α-iron, and, in consequence, the grain-size is very small, while the amorphous envelopes are proportionally increased. The retardation produced by carbon is taken to represent the time needed by the nascent α-ferrite to transfer carbon to the surrounding untransformed austenite. Carbon is readily soluble in austenite, but sparingly soluble in ferrite, so that the transformation of a given particle from austenite to ferrite cannot occur until it has succeeded in expelling the carbon to the surrounding untransformed austenite. This hypothesis was discussed by H. M. Howe, R. J. Anderson and J. T. Norton, F. Osmond, A. Sauveur, J. O. Arnold, F. W. Harbord and T. Twynam, C. H. Desch, and Z. Jeffries and R. S. Archer. In the production of amorphous metal it was supposed by C. A. Edwards and H. C. H. Carpenter that during the quenching the mass undergoes an internal straining on the slip or gliding planes which produces a twinning of the crystals; and that hard, amorphous or vitreous layers, formed during the internal slipping or twinning, are retained by quick cooling. C. Benedicks contended that the hypothesis that surface colours and that hardness are produced by amorphous metals in the plastic state is not in accord with metallographic facts.

It is generally held that the carbon in martensite is held in soln. either as carbon atoms or as carbide. The general opinion is that the carbide is present as the tritacarbide, Fe_3C, but J. O. Arnold postulated the existence of a subcarbide, $Fe_{24}C$—**subcarbide hypothesis of hardening**—because that corresponds with the eutectoidal proportion of carbon, viz. 0·89 per cent., and because some maxima in the physical properties—*e.g.* evolution of heat, and magnetic retentivity—are obtained with that proportion of carbon. It is assumed (i) that above the critical temp. the carbon of steel forms a subcarbide, the excess of iron separating as free iron, and the excess of carbon as cementite ; (ii) that by abrupt cooling this condition is preserved, so that hardened steel consists of and owes its properties to the subcarbide in the form of hardenite (*q.v.*) ; and (iii) that by slow cooling the excess of free iron and cementite persists, while the subcarbide is resolved into a mixture of ferrite and cementite, which, under favourable conditions, is interstratified to form pearlite. It is shown elsewhere that there is probably no such chemical individual as is here postulated, although H. Hanemann and A. Schrader also assume that the hardness is due to the presence of some such carbide. A rather vague hypothesis refers the hardening of steel to the assumption that carbon exists in the steel in two states—hardening carbon and cement carbon—*vide supra*, A. Ledebur. This is the so-called **carbon hypothesis of hardening.** Between 620° and 720° carbon passes spontaneously from the normal state of cement carbon to a special condition called hardening carbon ; the reverse change occurs during slow cooling. The cause of hardening by sudden cooling is attributed to the retention of carbon in the hardening state. It is generally recognized, as F. Osmond expressed it, that carbon presents, in its relations with iron, a certain number of peculiarities which are inseparable from its presence ; and a variation of the allotropic iron hypothesis was suggested by H. M. Howe, who assumed that the hardening of suddenly-cooled steel is due to the presence of hard carbides of γ- and β-iron, which are decomposed at the critical points only when the steel is cooled slowly. The carbides are supposed to have the properties needed to agree with the observed phenomena. This hypothesis was called the **carbo-allotropic hypothesis of hardening.**

C. Benedicks showed that in general solid soln. are much harder than the metals themselves—**solid solution hypothesis of hardening.** This was confirmed by N. S. Kurnakoff and S. F. Schemtschuschny. For small proportions of the element B dissolved in the solvent element A the coeff. of hardness, H, may be written $\delta h = H.\delta C$, where h denotes the hardness and C the at. percentage concentration of B. The more nearly similar, chemically, A is to B, the less the hardness coeff. H. The ready substitution of A by B generally means that the solubility of B in A is large, and conversely. Hence, when the solubility of B in A is large, the hardness coeff. H is small ; and when the stability of B in A is small, the hardness coeff. is large. If the added element B is very dissimilar to A, it must necessarily cause an essential change or distortion of the space-lattice of A, or it may interfere with the probably synchronous vibrations occurring in solid crystals. C. Benedicks inferred : In order that a metal A be hardened on quenching it is a necessary and sufficient condition that a substance B occurs which is but little soluble in A at temp. below a definite temp. T, but which is easily dissolved at a higher temp., and that it is impossible on sudden cooling from a temp. exceeding T to preserve the solid soln. AB at ordinary temp. On slightly reheating to a temp. less than T, a partial segregation of the solid soln. AB into a mixture A+B occurs, and the metal is tempered. This view is supported by L. Guillet, and A. M. Portevin. E. Maurer assumed that the hardness is due to the forced soln. of carbon—super-saturated soln.—which causes an appreciable increase in vol., and consequently a distortion of the crystal structure. Z. Jeffries and R. S. Archer said that solid soln. are harder than the solvent metal because slip is interfered with by the greater attraction between unlike than between like atoms, and by the roughening of the slip-planes due to solute atoms of different effective size than the solvent atoms.

Intermetallic compounds are hard and brittle because of the great attractive forces between the combining atoms, the non-interchangeability of positions of unlike atoms in the space-lattice, and the low crystalline symmetry of the space-lattice. The presence in an aggregate of any constituent having a high specific hardness interferes with slip in the surrounding material and thereby increases the hardness of the aggregate. This agrees with C. Benedicks' statement that every foreign atom by its frictional or locking effect retards the slipping action along a surface in the same way as a grain of sand retards the moving surface of a machine. C. Benedicks showed that while solid soln. are harder than the pure metals, the greatest increase in hardness is shown by supersaturated solid soln.; supercooled solid soln. are not so hard. The partial splitting up of a supersaturated solid soln., such as occurs on tempering steel, results in a decrease in the hardness of the metal. Austenite is regarded as a supercooled solid soln., and martensite as a supersaturated solid soln. The subject was discussed by H. Styri. J. O. Arnold's hardenite, 21Fe.Fe$_3$C, formed from pearlite, is a solid soln. which has the hardness characteristic of an amorphous solid soln. On tempering, a desired proportion of the carbide is precipitated from the solid soln. P. Chevenard suggested a modification of these hypotheses.

A. McCance suggested an **interstrain hypothesis of hardening**. He concluded that in a quenched and uniformly hardened steel the carbon is in solution, and it retains a portion of the iron in the γ-state; the greater the percentage of carbon the greater the proportion retained in solution. Most of the iron, however, is in the α-state, but owing to the restricted mobility during quenching, the crystalline units are not homogeneously orientated. In other words, owing to the rapidity of the cooling process the crystals of α-iron have not time to assume homogeneous orientation. At quenching, the crystal grains have the symmetry of γ-iron, and any γ-iron retained in the cold will have that symmetry, but the rest will be changed to α-iron, although lack of time, internal friction, and the obstruction caused by the crystals of γ-iron will prevent the crystals of α-iron arranging themselves homogeneously. The interstrain so induced by the α-iron makes the material very hard. W. von Möllendorff objected to the term amorphous when applied to metals with broken space-lattices, since it is not in accord with the mechanical properties of plastic materials. He attributed the hardness to a disturbed orientation and vectorial shape distortion of the crystalline molecules. H. Hanemann and A. Schrader attribute the hardness of martensite to a definite arrangement of iron and carbon atoms in a definite iron carbide. The actual bearer of the martensitic hardness is attributed to η-martensite—*vide supra*.

Z. Jeffries and R. S. Archer described what they called the **slip interference hypothesis of hardening** in the following words:

Metals are crystalline and are built up of atoms arranged in definite and repeating patterns. The regularity of atomic arrangement gives rise to certain planes of weakness, or low resistance to shearing stress. When an external load produces a shearing stress on such a plane, which exceeds the resistance of the crystal to shear on that particular plane, fracture of the crystal takes place. The fragments formed may or may not adhere to each other. If they do not, the failure of the crystal is complete, and it is said to be brittle. The plane of weakness is then known as a " cleavage plane." More generally, in the useful metals, the crystal fragments adhere and merely glide or " slip " over each other. The result of such slip, repeated on many planes, is a measurable permanent deformation. The crystal is ductile, and the planes of weakness are called " slip planes." The first appreciable formation of slip-planes marks the beginning of plastic deformation and, therefore, the passing of the elastic limit. The resistance to permanent deformation, which is a general measure of hardness and strength, represents resistance to the beginning and propagation of slip. Anything that serves to hinder slip is a source of strength and hardness.

In applying the hypothesis that *the hardening and strengthening of metals by any of the known methods may be considered as due principally to interference with slip*, Z. Jeffries and R. S. Archer say that the hardness of amorphous metals is attributed to the absence of planes of weakness characteristic of crystalline metals.

The increased hardness and strength of pearlite over pure iron are attributed largely to the increased resistance to slip in the ferrite grains offered by the hard cementite. The increased hardness of sorbite and troostite over pearlite is due to the refinement of the ferrite grains and the greater dispersion of the cementite particles. The increased hardness of martensite over troostite is attributed to the greater refinement of the ferrite grains, and, in cases of maximum hardness, to the critical dispersion of the cementite particles. The carbon in soln. or in a state of atomic dispersion in the ferrite of martensite makes it harder than the ferrite of pure iron. Carbon is less soluble in α-iron than in γ-iron ; the α-iron of freshly-formed martensite contains carbon atoms in a state of atomic dispersion, so that it is supersaturated with respect to carbon ; equilibrium is brought about by the precipitation of carbon as cementite. The carbon dispersed in α-iron at room temp. diffuses more rapidly as the temp. is increased. The carbide therefore precipitates slowly at room temp. and more rapidly with rising temp. The increase in hardness of freshly-quenched martensite on standing or after a mild tempering is attributed to the precipitation of hard cementite, which hinders movement on the slip-planes of the ferrite grains. Heating softens martensite by producing a growth of the ferrite grains. Heating produces changes in the carbide which tend to harden the steel until the critical dispersion of the carbide particles is produced ; further heating softens the martensite. The growth of the carbide particles occurs as a result of the slight solubility of carbon in α-iron, which is greater the smaller the size of the cementite particles with which the soln. is in contact. The α-iron should reach approximately its equilibrium value before the growth of the particles begins, so that the carbide must be nearly completely precipitated at an early stage of the tempering. The more rapid the cooling of austenite, the lower the temp. of its transformation into ferrite and cementite. When the transformation occurs at or above 600°, both ferrite and cementite are formed as pearlite, sorbite, or troostite. If the austenite is preserved below about 600°, it seems relatively stable until a temp. of about 300° is obtained on cooling. When the austenite transformation is suppressed to about 300° or less, the allotropic transformation of iron occurs independently of the carbide formation. The composition of the steel may be such that by rapid cooling the austenite is preserved at room temp., but not so with slow cooling. The transformation of this austenite to martensite or another product on ageing or tempering results in an increase in hardness, which is also attended by an increase in volume. R. F. Mehl and B. J. Mair consider that the identity of the compressibility coeff. of quenched and annealed eutectoidal steel shows that the structural units and the binding forces between the atoms are not greatly different, and consequently that the hardness, as in the slip interference theory, is produced only by differences in the mechanical arrangement of the structural units. R. Vondracek attributed the hardness to the altered structure of the metal during crystallization. K. Honda, E. C. Bain, E. Heyn, A. Westgren, P. D. Merica, F. T. Sisco, M. G. Corson, O. E. Harder and R. L. Dowdell, and D. J. McAdam made observations on this subject—*vide supra*, martensite.

Another hypothesis, due to F. Reiser, refers the hardening of steel by rapid cooling—**stress hypothesis of hardening**—to the internal stresses which arise owing to the rapid contraction of red-hot material owing to (i) the shrinkage of the outer skin, and (ii) the increase in volume during the complete or partial change of austenite to martensite. C. Barus and V. Strouhal said that in steel there is a limited interchange of the atoms between the molecules under stress, which must be a property common to solids, if solids are made up of configurations in all degrees of molecular stability. In hardened steel the strain applied to the steel is locked up in the metal in virtue of its viscosity ; tempering is the release of the molecular strain by heat. The hypothesis was discussed by O. Thallner, and W. Tafel. The stress hypothesis was discussed by R. Akerman, A. le Chatelier, W. Metcalfe, G. Charpy, L. Guillet, and H. M. Howe. The hypothesis does not explain why steel quenched from just below the Ac_1-arrest is soft, and when quenched from

above that temp. is hard; why the hardness produced by quenching steel is so much greater than is the case with other alloys; and why quenched materials do not have the greatest hardness at the centre of the mass, where the internal press. is a maximum. Cold-work sets up a certain amount of strain and produces a slight increase in the hardness, a definite loss in ductility, and an increase in the elastic limit.

C. A. Edwards and H. C. H. Carpenter assume that austenite and martensite are constitutionally identical; the latter alone exhibits twinning. The hardness of martensite is attributed to the formation of amorphous material at the surfaces of slip on which twinning occurs. C. A. Edwards assumed that the hardness is due to the retention, by quenching, of the solid soln. of iron carbide in iron. The hardness depends on the fact that iron can exist in the γ-state and dissolve carbon; it is none the less dependent on the fact that the solid soln. decomposes with a slow rate of cooling into α-iron and iron carbide. Some energy must be absorbed in the quenching process in order to overcome the tendency for the Ar_1-inversion to occur. This energy acts in two ways: (i) by the sudden contraction of the outer envelope of the specimen; and (ii) by an internal mol. contraction of the mass which is related with the soln. press. or the osmotic press. of the dissolved carbide. The degree of hardness produced by quenching a given carbon steel will depend on the velocity and thermal magnitude of the suppressed inversion, i.e. on the amount of energy it is necessary to absorb in order to prevent the inversion taking place. This shows why the so-called austenitic, quenched, carbon steels are slightly softer than when the same steel is martensitic. The osmotic or soln. press. of carbon steels increases as the percentage of carbon increases from zero to 0·89, and then rapidly decreases as the percentage rises to 2·0, for, in general, the osmotic press. of soln. increases as the f.p. is lowered, as also the temp. at which the solid soln. deposits one of its constituents. The maximum osmotic press. in liquid soln. occurs with those having a eutectic composition, and in the analogous solid soln. with those having the eutectoidal composition. The maximum thermal change at the critical temp., indicated on the cooling curve, occurs with eutectoidal steel with 0·89 per cent. of carbon. Consequently, the maximum combined physical effect of iron and carbon occurs with steels having 0·89 per cent. of carbon; and since the hardening effect is directly connected with the osmotic press., the thermal critical points, etc., it is to be anticipated that the maximum hardness should be obtained by quenching steels of that composition, and that austenitic steels should be a little softer than equivalent martensitic steels.

L. Grenet added that it is unnecessary to take the allotropic transformations of iron into consideration when discussing the hardness of steel. Quenching as compared with slow cooling may act (i) by changing the nature of the constituents, and notably by preventing, wholly or partly, the transformation on cooling. In this case, which is rare so far as steels are concerned, the quenched state and that obtained by slow cooling are really different states, and their properties cannot be foreseen. In a few cases the quenched state is softer than that obtained by slow cooling—e.g. J. H. Andrew's results with some copper-tin alloys. (ii) Quenching may also act by lowering the temp. of the transformation on cooling, and the quenched state is then always the harder. In general, "an alloy is the harder in proportion as the transformation which has given birth to its constituents at the time has taken place at a lower temp., has been more rapid, and as the maximum temp. reached since the last transformation has been at a lower temp. and has been maintained for a shorter period of time." The law also applied to pure metals. According to L. Grenet's hypothesis, hardness is not due to the complete suppression of the thermal transformation, but rather to its taking place at a lower temp.; quenching depresses but does not suppress the change. In consequence of the delayed transformation, the decomposition of the martensite furnishes products which are in a very fine state of subdivision, and the resulting fine state of aggregation accounts for the excessive hardness—**fine-grained hypothesis of hardening—**

vide infra, hardness. J. H. Andrew assumed that the hardness of a quenched steel largely depends on the transformation of austenite into martensite, and the formation of martensite as finely-divided free cementite embedded in a matrix of undecomposed austenite and α-iron. The hardness is thus attributed to the formation of a system with exceedingly hard, finely-divided cementite embedded in a relatively hard matrix of austenite, and α-iron. W. Rosenhain expressed his view of the hardening in the following words : " Hardening is due to the decomposition of a supersaturated or metastable solid soln. obtained by quenching, such decomposition resulting in the production of a very large number of crystallites of one or more phases, either constituting the whole of the hardened material, or scattered through a crystalline matrix." He added :

That a structure of this kind should possess, in some cases, an extreme degree of hardness is readily understood, since the softness and plasticity of metals in their ordinary condition are known to be due to the possibility of plastic deformation by a mechanism of internal slip in the crystals. Any disturbance of the regular crystalline arrangement results in a corresponding increase of resistance to slip, and therefore increase of hardness. If the disturbance of the structure be carried to the point where the slip mechanism is entirely destroyed or its functioning is eliminated, complete hardening results, and the degree of hardening in a given case will depend, in the first place, upon the exact extent to which the slip mechanism is disturbed, and, in the second place, upon the actual cohesive strength of the metal in question. In hardened steel, both factors operate to produce maximum hardness. Iron itself, although very soft and ductile when in the pure state, possesses a high degree of cohesion ; further, the simultaneous formation of α-iron and cementite during the decomposition of γ-iron, as a result of the allotropic transformation of the iron itself, brings about a structural arrangement most completely preventing the occurrence of plastic deformation by slip.

The relation of this hypothesis to the allotropic theory turns on the fact that the allotropic transformation gives rise to an abrupt change in the solid solubility ; it is related to the carbide hypothesis in that the presence of carbon is necessary to furnish one of the two decomposition products of the solid soln. ; and it is related to the amorphous hypothesis in that the kind of disturbance of the crystal structure of a solid soln. which is produced by the formation in it of minute crystallites of a deposited phase may be described as rendering the substance more or less completely amorphous in the immediate vicinity of each of these crystallites. One of the main features of the amorphous state is the very absence of slip mechanism, which in the present view is regarded as being essential to hardness. F. Osmond, however, inferred that the Ar_1-inversion is wholly or partly suppressed, because (i) the cooling curves taken during the quenching period show no signs of the evolution of heat ; (ii) the dissolution of soft and hard steels in a sat. soln. of ammonium cupric chloride shows that more heat is evolved by the hardened steel ; and (iii) the latent heat of hardening, so to speak, appears on the heating curves of hardened steel as accelerations. The subject was discussed by K. Scheel.

Modifications of this hypothesis—called the dispersion theory and the precipitation theory—have been discussed by Z. Jeffries and R. S. Archer, O. E. Harder, H. Esser and W. Eilender, W. Eilender and R. Wasmuht, and others. It is assumed that a metal may be effectively hardened by highly dispersed particles within the grains, such as may be precipitated from supersaturated soln. It is exemplified by the hardening of metals by heat treatment, in which the metal is cooled from a relatively high temp. into a region of supersaturation, and then by tempering or ageing to permit the formation of a fine precipitate. The precipitated granules tend to grow through a critical size, whereby a maximum hardness is attained ; any further growth is attended by a decrease in the hardness of the metal.

W. Rosenhain, W. L. Fink and K. R. van Horn, H. W. Gillett, S. Kimura, R. S. Dean and co-workers, G. Sachs, and K. Honda explained the hardness of martensite by the **distorted lattice hypothesis.** K. Honda said :

The distribution of the carbon atoms in the martensite has not yet been confirmed by X-ray analysis. These atoms cannot approach too near to iron atoms in virtue of the

repulsive force coming into play between the two kinds of atoms when they approach very near together; also they must take a symmetrical position in relation to the iron atoms. Hence in order to satisfy these two conditions, the carbon atoms in martensite may take positions in the centre of the face of an elementary cube, distributed here and there according to the law of probability. A local distortion of the lattice may of course result. These carbon atoms will send their lines of force toward six neighbouring atoms and themselves behave like diagonal supporters in square framework, thus giving to the lattice-building a great strength as a whole. From the above consideration the strength of martensite must increase with the concentration of carbon. This fact is confirmed by experiments as far as a medium carbon steel is concerned. In higher carbon concentrations the presence of austenite intermingled with martensite causes a decrease of hardness. Again, in a complete quenching, the size of the martensite crystals increases with carbon content and consequently causes a decrease of hardness in high carbon steels. It may be remarked that by quenching iron-nickel alloys containing about 15 to 30 per cent. of nickel from the austenitic region into water or liquid air, a martensitic structure is obtained, and the hardness greatly increases, though no appreciable content of carbon is present. This is also explained in the same way as in the case of carbon steels. Above the A_3-line iron atoms assume the distribution of a face-centred cube, some of them being replaced by nickel atoms according to the concentration, but below this line they take that of a body-centred cube; the sides of the unit cubes in these two cases have a ratio of about 1·3. By quenching the alloys from the austenitic region into water or liquid air the lattice changes, as a whole, from the face-centred cube to the body-centred, but owing to the very rapid cooling, some of the nickel atoms may not have a sufficient time to assume their proper position and may remain in the centre of the face of the body-centred cube and play the part of carbon atoms in the martensite of carbon steels, thus giving to the alloys a great strength or great hardness.

The hardening or formation of martensite from austenite at the A_1-arrest involves a change from a solid soln. of carbon in γ-iron to ferrite and cementite. This involves the two independent transformations : (i) a change in the atomic configuration of iron from the face-centred to the body-centred lattice ; and (ii) the separation of carbon atoms as cementite from the interspace of the lattice. The change in the lattice configuration is attended by a great reduction in the solubility of carbon, and the formation of the α-iron lattice is attended by the precipitation of carbon as cementite. The A_1-transformation is a double process. With the slow cooling of carbon steels the austenite changes to martensite, and the lattice immediately forms pearlite ; but with very rapid cooling, or quenching, the change from austenite to martensite is retarded, and begins about 300°, and is virtually completed near room temp. The second change from martensite to pearlite cannot take place, because this change involves the diffusion of carbon atoms through iron and therefore the specimen will undergo a high resistance owing to its greater viscosity at room temperature. Thus the martensite is obtained by quenching the steel in water. Perfect quenching or hardening is obtained when the first half of the A_1-transformation—austenite to martensite—is completed, and the second half—martensite to pearlite—is suppressed. In the case of a less rapid cooling the first half of the transformation occurs at a temperature a little higher than in the above case, and therefore the second half partly takes place, resulting in a martensitic structure mixed with troostite. Troostite is a dispersed system, in which cementite is suspended in iron as very fine colloid-like particles, and hence is a mechanical mixture of cementite and iron and does not differ physically from pearlite. The hardness of martensite mixed with troostite is less than that of pure martensite. In this case there is an imperfect hardening. In the case of an extremely rapid cooling not only is the second half of the A_1-transformation completely suppressed, but also the first half is partially arrested ; there is thus formed a mixture of martensite and austenite the hardness of which is less than that of pure martensite. In this case there is a too severe quenching. L. Grenet pointed out that in quenching from, say, 1450° the α-phase, that is δ-iron, transforms to γ-iron with the evolution of heat ; but this transformation can be suppressed by quenching the metal in a bath at 850° : the iron then remains in the stable α-state without passing through the intermediate γ-state. Hence, quenching need not be attended by hardening.

R. F. Mehl and B. J. Mair consider that the identity of the compressibility coeff. of annealed and quenched eutectoidal steel shows that there is no marked alteration in the interatomic forces such as would have to be postulated by the lattice distortion hypothesis. H. Esser and W. Eilender concluded that the hardening of steel by quenching is controlled by the degree of dispersion of the precipitated iron carbide, and by the considerable distortion of the α-iron lattice produced by the separated carbide in the γ-α-transformation at a temp. at which the plasticity of the metal is very low. K. Heindlhofer and E. C. Bain added that the hardness of martensite must be explained on the basis of a strong interatomic bonding within the greatly supersaturated pseudo-solid soln. of carbon in ferrite, along with grain-size and distortion due to cold-work.

The different theories of hardening have been discussed by B. D. Enlund, W. T. Griffiths, etc. There is here a plurality of causes. O. E. Harder and R. L. Dowdell, and F. T. Sisco consider that hardness may be produced by (i) slip interference caused by the formation of martensite needles ; (ii) by grain refinement resulting from the recrystallization, as many small grains of α-iron are inherited from the parent austenite at a temp. below that at which normal recrystallization occurs ; (iii) the disturbance produced by stress distorting the lattice of α-iron and some residual γ-iron ; (iv) the saturation or supersaturation of the martensite with respect to the carbon atoms within the α-lattice; (v) the presence of numerous small particles of carbide which act as keys locking up the slip-planes, so that the hardness increases as the size of these particles up to a certain critical grain-size, after which it decreases as the particles of carbide grow larger ; and (vi) by the interatomic forces in the martensite. K. Honda also emphasized the probability that the cause of the great hardness is not due to any one condition, but rather to several. There is the hardness produced by fineness of grain, by internal strains, and by the presence of the carbon atoms within the lattice. He attempted a numerical estimate of these agencies in the case of the martensite of a 0·9 per cent. carbon steel with the Brinell's hardness of 680. The natural hardness of the steel is taken to be 280 ; the increase due to the fine-grained structure, 80 ; the increase due to interstrain, 150 ; and the increase due to the carbon atoms within the lattice, 230.

Heat treatment with the object of hardening the metal produces a fine-grained metal with the maximum hardness and tensile strength and the minimum ductility. The hardened metal, however, is usually too hard and too brittle, and it is also severely strained internally. W. R. Angell[5] found that the tensile strength and impact tests of steels quenched below the Ac_3- and above Ar_3-arrest are equally good, but the lower quenching temp. minimizes the quenching strains, and gives a more plastic material which can be handled without deformation. In order to relieve the quenching strains, to decrease the brittleness, and to restore the ductility without reducing the hardness and strength too much, the metal is tempered by heating it into a range of temp. extending from room temp. to a temp. below the Ac_1-arrest, and cooling it at any desired rate. The operation is called **tempering** —*Anlassen*—because it moderates, mitigates, relieves, or tempers the effects of the hardening process. An increase in toughness may be produced by a combination of hardening and tempering—*Vergüten*. In some cases the word " tempering " refers to the re-heating of hardened steel below 400°, and " drawing " or " drawing to the temper " for the re-heating of the steel above 400°. According to C. Barus and C. Strouhal, the tempering is accompanied by a chemical change even at temp. slightly above atmospheric. The mol. configuration of glass-hard steel is always in a state of incipient change, and a part of the change is permanent. If glass-hard steel be heated suddenly to 300°, it behaves almost like a viscous fluid. C. Barus added that the tempering may occur even at the ordinary temp., for the hardness of quenched steel, when kept at ordinary temp. for a few years, may be reduced as much as occurs if the steel be heated at 100° for a few hours. This phenomenon is rather different from the ageing to which reference has been made. This subject

was discussed by F. Giolitti. A. Poucholle studied the variation in the length of steel rods as a function of the time of cooling after different heat treatments. He said that tempering is characterized by the absence of the transformation point Ar_1 at low temp. The transformation of γ-iron into α-iron only takes place at the point Ar_2, that is, at about 200°. Over the temp. range 650° to 200°, from the point Ar_1 to the point Ar_2, the curves do not show any angular point. However, invariably in this region, and only in this region, mechanical tensions appear, being manifested by sharp cracks and accompanied by the projection of the thin skin of oxide. The transformation point Ar_1 is lowered if the annealing observed follows a tempering. Similarly, the temp. at which tempering is obtained is lowered by successive temperings. The amplitude of the inflection Ar_1 diminishes (a) by rise in temp. until it becomes nil, (b) by the duration of the heating if the temp. remains constant. G. Kurdjumoff found by X-radiogram measurements that the tempering of hardened carbon steel takes place in three stages : (i) the breaking down of the tetragonal structure, which occurs at an appreciable velocity at 100° to 150° ; (ii) the breaking down of the austenite at 250° ; and (iii) the formation of an α-iron-cementite mixture, which occurs slowly at 300° to 400°.

Hardened steel is in an unstable or metastable condition ready to change to a more stable state as soon as the conditions are favourable—such as occurs, for instance, when the temp. is raised. Few pieces of structural metal are in a state of internal repose though not at the time acted upon by external forces. This subject was investigated by J. E. Howard. Internal strains up to the elastic limit may persist after all molecular flow has ceased. There is some stress above zero load which the metal will endure an indefinite time, whether this stress is the result of internal strains in some parts or is due to external forces. By annealing, the elastic limit is lowered as the temp. rises, and with a lowering of the elastic limit some of the strain is removed by an amount nearly proportional to the elastic limit. It is not strictly proportional, because the modulus of elasticity decreases as the temp. increases. The relief of the internal strains at ordinary temp. is hindered by the rigidity of the metal, but by raising the temp. a little the transformation can proceed at an appreciable rate. The speed of the transformation is faster the higher the temp. ; but in all cases it is a time reaction ; and hardening of steel is the result of an arrested reaction—4. 31, 33. C. Barus and V. Strouhal said that a transformation which occupies 3 hrs. at 100° is completed in a few seconds at 650°. E. Heyn and O. Bauer, and H. Hanemann also noted that the tempering may occupy only a few seconds when conducted at the right temp., where it does not proceed beyond the required stage during, say, 120 hrs. Hardened steel may contain a large proportion of martensite, as well as more or less austenite and troostite. If the steel is tempered with the idea of preserving its hardness, the operation is sometimes called *troostitizing*, because the steel is tempered in the range of temp. favourable to the growth of this constituent—between 100° and about 400° ; whereas if the steel is tempered for strength and ductility and retains the fine structure of martensite, the operation is sometimes called *sorbitizing ;* the change occurs at a temp. between 400° and about 650° or even 700°. J. E. Stead and A. W. Richards, E. Marcotte, N. V. Kolokoloff, and N. N. Shadrin discussed this subject. G. Charpy and L. Grenet investigated the depth of the penetration of tempering.

The so-called *patenting of steel* is a process of heat treatment in which a structure verging on " over-heating " is imparted to rods or wire. In this process the temp. of the metal is raised steadily to a range dependent on the diameter of the wire, and well above the critical temp. of the steel ; this temp. is maintained for a period necessary to allow a complete diffusion of the carbon and the growth of the crystal grain to a maximum dependent on the sectional area of the wire. This metal is then rapidly cooled to retain the dispersed carbide in the state of sorbite. The process was discussed by J. S. G. Primrose, and J. D. Brunton.

H. Brearley gave 2499 for Brinell's hardness of a 1·1 per cent. carbon steel

which had been heated to 760° and then quenched in water; the hardness of the same steel after annealing at different temp. was as follows:

	50°	100°	200°	300°	400°	500°	600°
Hardness .	2499	2490	2380	1190	917	770	358

H. C. Boynton stated that the decrease of hardness on tempering is gradual up to 350°, it is quite sudden between 350° and 550°, and zero above 550°. E. Heyn found the loss of hardness expressed as a percentage of the original increase produced by the hardening to be:

	100°	200°	300°	400°	500°	600°
Increased hardness .	2·5	14·0	41·0	70·0	87·5	97·5 per cent.

K. Tamaru, and C. Grard noted an increase in Brinell's hardness of quenched 0·89 per cent. carbon steel from 661 to 683 when it is tempered at about 112° —*vide infra*, hardness. K. Tamaru found that the Rockwell hardnesses of armco and electrolytic iron, melted in vacuo, and of 0·2 per cent. carbon steel, melted in vacuo and in air, were:

		Annealed	Cold-worked	150°	300°	400°	600°	900°
Electrolytic in vacuo	.	58	86	84	83	80	56	43
Armco in vacuo	. .	62	91	89	86	84	58	46
0·2 per cent. C {in vacuo	.	67·6	94	—	96	94	74·3	—
{in air	.	83	10·2	—	105	104	87	—

with header "Tempered at" spanning 150° 300° 400° 600° 900°.

B. N. Enlund inferred that martensite is transformed into troostite at 100° to 200°, and that the reaction is most marked at about 110°, and that the retained austenite is decomposed at about 260°. This does not explain the initial hardening, for
FIG. 47.—Dilation of Carbon Steel on Tempering.
FIG. 48.—The Effect of Tempering on the Specific Gravity.

troostite should cause a softening. K. Tamaru concluded that the initial hardening is due to the transformation of unconverted or retained austenite into martensite. The dilations $\delta l/l$ of 0·89 and 1·69 per cent. of carbon steels are shown in Fig. 47. These specimens do not show the expansion which should be caused by the transformation of retained austenite into martensite; rather do the specimens contract. This is because only a small proportion of austenite changes into martensite, and a considerable proportion of martensite changes into troostite. The latter change is attended by a contraction. The increased troostite does not have so marked an effect on the hardness. Near 240° the transformation of retained austenite into martensite produces an expansion, and that of martensite into troostite at 270°, a contraction. The sp. gr. determinations summarized in Fig. 48 show a maximum between 120° and 200°, and a minimum at about 270°, but not the effects of the expansion at 110°. These curves are similar to those obtained by E. Maurer—*vide infra*, sp. gr. K. Tamaru measured the sp. gr. of electrolytic and of armco iron, and of some carbon steels after cold-working and

tempering at different temp. The selection from the results shows that the sp. gr. are as follow :

		Annealed	Cold-worked	Tempered at 150°	300°	400°	600°	900°
Electrolytic	in vacuo .	7·883	7·881	7·880	7·879	7·881	7·880	7·882
	in air .	7·834	7·835	7·834	7·838	7·837	7·840	7·840
Armco	in vacuo .	7·878	7·875	7·875	7·875	7·874	7·875	7·877
	in air .	7·808	7·807	7·806	7·809	7·806	7·811	7·817
0·1 per cent. C	as received	7·873	7·853	7·858	7·857	7·857	7·859	7·863
	in vacuo .	7·861	7·855	—	7·853	7·853	7·856	—
	in air .	7·820	7·801	—	7·803	7·803	7·807	7·814

	in vacuo .	7·844	7·831	—	7·830	7·832	7·837	—
	in air .	7·822	7·811	—	7·813	7·815	7·820	—
0·4 per cent. C,	as received	7·840	7·828	—	7·830	7·829	7·837	7·845

The sp. gr. of armco iron is decreased by cold-work, and the sp. gr. attains a maximum with tempering at 150° and a minimum at 400°; the corresponding effects with steel are smaller. With armco and electrolytic iron remelted and solidified in vacuo, the change in sp. gr. produced by cold-work is slight ; but if remelted in air, the sp. gr. is normally decreased by cold-work. L. Aitchison, M. G. Oknoff, E. H. Schulz, L. A. Lanning, M. A. Grossman, L. Aitchison and G. R. Woodvine, S. Sato, F. A. Livermore, W. Köhler, L. Traeger, A. M. Portevin and A. Sourdillon, C. M. Saeger and E. J. Ash, and G. M. Eaton also measured the change in the vol. or sp. gr. of iron and steel by heat treatment. Observations of the mechanical properties of steels tempered at different temp. were made by A. Jung, O. Thallner, O. Hoffmann, R. Kühnel, A. Michel and P. Bénazet, N. B. Pilling, M. A. Grossmann, G. Welter, A. T. Adam, R. Hay and R. Higgins, P. Goerens, H. Scott, H. Scott and H. G. Movius, W. P. Wood, L. Aitchison, H. Birnbaum, G. M. Eaton, R. Stotz and F. Henfling, M. G. Oknoff, H. I. Coe, M. Sauvageot and H. Delmas, F. T. Sisco, A. Bauschlicher, H. J. French, S. Curie, J. A. Mathews and H. J. Stagg, H. Bennek, E. Maurer, F. Giolitti, O. E. Harder and R. L. Dowdell, etc. ; A. M. Portevin and co-workers, H. M. Howe and A. G. Levy, and C. R. Hayward and co-workers, the effect of time on tempering ; S. L. Hoyt, and E. Murata, the effects of tempering on the internal stresses ; W. Fraenkel and E. Heymann, the change in the sp. gr. and electrical resistance during tempering ; W. P. Wood, and P. Chevenard, the volume changes ; F. G. Sefing, the energy changes ; W. Fraenkel and E. Heymann, the kinetics of tempering ; A. M. Portevin, the relation of annealing to the phase rule and equilibrium diagram ; and E. F. Law, K. W. Zimmerschied, R. C. Gosrow, W. B. Crowe, E. J. Janitzky, H. J. French and O. Z. Klopsch, J. A. Jones, and A. Schack, the influence of mass.

In the **Majorana effect,** observed by O. Majorana, two similar specimens of iron or steel are prepared, one is heated to orange redness, and the other remains untreated ; the heated metal is then allowed to cool slowly ; both specimens are polished ; if now they be introduced into a very delicate thermostatic apparatus, the heat-treated specimen remains at a temp. 0·1° above the other for a few days. After some weeks, the temp. difference disappears. The effect is more pronounced with steel than with iron, and is of doubtful occurrence in lead or copper. M. A. Schirmann confirmed this result and suggested that the heating drives off dissolved gases and that these are gradually reabsorbed with evolution of heat. This is confirmed by H. Kleine's observations that the electrical resistance of vacuum-annealed iron (or platinum) increases practically linearly if it be allowed to stand in air over a period of five days. Similarly, when the gassed metal is reheated *in vacuo*, the resistance falls. E. D. Campbell and B. A. Soule observed similar effects.

According to E. Heyn, and O. Bauer, steel which had been hardened, but not tempered, showed well-developed martensite needles, which remained uncoloured

after being immersed for 10 mins. in a 1 per cent. soln. of hydrochloric acid in alcohol. When tempered between 100° and 200° the martensitic structure was not changed, but it was coloured yellow or brown by treatment with the alcoholic hydrochloric acid. After tempering at 275° the acicular structure became coarser and behaved like mixtures of austenite and martensite, in that one constituent remained uncoloured while the other became dark. After tempering at 405° the martensitic needles disappeared and the sample appeared dark and mottled, suggesting a mixture of two relatively dark constituents—*viz.* troostite. After tempering at 500° the light-coloured areas became more abundant; and after tempering at 600° irregular, rounded, light-coloured masses appeared which were surrounded by a darker network which was in relief. For theories of tempering, *vide supra*, theories of hardening.

P. Goerens said that hardened mild steel becomes soft at 520°; and H. M. Howe found that the temp. required to release the internal strains or completely to soften steel hardened by various degrees of cold-working, measured by the reduction of area by cold-work, are:

Cold-work	4	8	12	15	25	50 per cent.
Temperature	750°	750°	650°	550°	550°	450°

J. H. Andrew and A. J. K. Honeyman found that the tempering of martensite begins at or below 150°, but is not complete at 360° in an hour. In a martensito-austenitic steel the austenite may be partially transferred at 150°, but below 260° the rate of change is very slow. It is complete below 370° in carbon steels. The tempering of a pure austenitic Ni-Cr-steel does not begin until near 300°, and is not complete in an hour at 360° to 370°. The presence of martensite thus appears to hasten the beginning of the austenitic transformation, but the pressure of the martensite thus produced inhibits the further tempering of austenite until more martensite is tempered. G. Tammann and E. Scheil found that martensite begins to pass into pearlite at about 100°, and austenite at about 250°; H. Hanemann and L. Träger found that hardened steel is fundamentally changed when kept in boiling water for 14 hrs. R. Hay and R. Higgins discussed the low-temp. changes in quenched carbon steels. T. Matsushita and K. Nagasawa studied various physical properties of quenched carbon steels tempered at different temp., and concluded that the boundary temp. for martensite and troostite are produced between about 100° and 300°; troostite at about 300°; troostite and sorbite between about 300° and 400°; sorbite (osmondite) at about 400°; sorbite and granular pearlite between about 400° and 500°; and granular pearlite from about 550° to the Ac_1-arrest. If the rate of heating be slower, the temp. here indicated should be lowered. They also said that when quenched steels are heated at the normal rate, α-martensite is formed on tempering between 100° and 170°, and β-martensite between 170° and 300°. The product of the decomposition of martensite on tempering is free carbon, not cementite; and the precipitated carbon unites with iron, mainly between 300° and 400°, to form cementite. The subject was discussed by P. Chevenard and A. M. Portevin, H. Hanemann, A. Michel and P. Bénazet, G. Kurdjumoff, M. Godefroid, A. le Thomas, P. Roudié, and S. H. Rees.

W. Fraenkel and E. Heymann measured the electrical resistance and sp. gr. of various steels at different stages of the process of tempering at different temp., and they found that in quenched martensitic steels the change from martensite to osmondite will continue till completion at all temperatures between 100° and 400°, but below 200° the change takes several months. The rate at which the transformation takes place is a function of the temp., and the temp. coeff. is of the same order of magnitude as that of a chemical reaction in a homogeneous solid phase. The nature of the change that ensues in the structure of the metal during tempering between 100° and 400° can best be explained on the assumption that the dissolved carbon in the martensite reacts within the iron to form a metastable carbide, $FeC_{8\cdot10}$,

and that an intimate mixture of this substance and iron constitutes osmondite.
Further heating of the metal above 400° results in the gradual formation of cementite,
followed by its agglomeration and crystallization to give with the excess iron the
pearlite structure. The above theory is substantiated by an examination of the
tempering curve as given by the change in electrical resistance ; this curve follows
the kinetic law, $-dC/dt=KC^{10}$, where C is the amount of carbon in soln. after
annealing for time, t. The velocity of the change from martensite to osmondite is
independent of the quenching temp. within the range of the γ-phase, of the time
of heating, and, within limits, of the carbon content of the steel. The sp. gr. of
the samples shows that austenite changes first to martensite and then to osmondite
during the process of tempering.

J. H. Andrew and co-workers studied the tempering of steels from the changes
in their electrical resistance. The results show that the tempering involves a
number of concurrent reactions, mutually dependent on one another. The process
of tempering in martensitic steels may be divided into three reactions. The first
of these is the separation of carbon from soln., accompanied by a fall in resistance
proportional to the amount separating. The precipitated carbon is not removed
from the system, but remains present as free carbide, the accumulation of which
results in an increase of resistance proportional to the amount of carbon precipitated.
This constitutes the second reaction. These two reactions proceed simultaneously,
FIG. 49.—The Rate of Separation of   FIG. 50.—The Rate of Separation of
      Carbon from Martensitic Steel.   Carbon from Austenitic Steel.
and give rise to an initial rapid fall of resistance. The state attained at the end of
the primary rapid separation of carbon is not permanent, but the subsequent
reaction is slower, and can be conveniently isolated. This final reaction is accom-
panied by a gradual fall of resistance, probably due to a gradual increase in the size
of the precipitated particles. These three simple processes combine to give the
experimentally determined curves. The rate at which carbon comes out of soln.
was estimated by multiplying the fall in resistance per minute by a factor, 0·0334,
expressing the ratio between the carbon in soln. and the resistance. The calculated
rates of separation of carbon from martensitic steels are shown in Fig. 49, and from
austenitic steels, in Fig. 50. The results show that martensitic steel tempers much
more rapidly than austenitic steel, and that martensite cannot accumulate at the
tempering temp. The martensite found in an austenitic chromium steel tempered
for 3 hrs. at 250° must have been formed during the cooling. Austenite, indeed, can
temper in two different ways : slowly at a constant temp., and more rapidly when
the temp. is falling. At a constant temp. austenite appears in effect to temper
directly to troostite ; martensite is only retained when the austenite is decomposed
by cooling. The rapid breakdown during cooling is of the same nature as the lower
change point designated Ar″, Fig. 46 ; the slow change at constant temp. is similar
to that which occurs at the ordinary A_1- or A′-point. The resistance curves and the
electrode potential curves indicate that the state attained by tempering at temp.
below 650° is different from that obtained by annealing. At each temp. the steel
attains a definite condition, retaining a certain amount of carbon in soln. in the

ferrite, and this condition approaches closer to the annealed state, with progressive decrease in the amount of dissolved carbon, as the tempering temp. is raised. Between martensite and pearlite two states, troostite and sorbite, are generally recognized; but it is clear that the transition from martensite to granular pearlite is progressive, and that troostite and sorbite are merely characteristic phases in the gradual change. Pearlite, sorbite, and troostite do not differ in state of division alone. They differ also in the amount of carbon in soln. in the ferrite, and to this may be attributed the remarkable difference in their properties, which is commonly ascribed to the state of division. A. Michel and P. Bénazet studied the effect of cobalt, nickel, chromium, and tungsten on the transformations.

The film of oxide formed on the smooth, bright surface of the metal varies in colour with the temp. of tempering. These **temper colours** are a guide to the workmen who temper tools, etc. They are discussed in connection with the tarnishing of iron. It is there shown that the time factor is ignored, since the same colour can be obtained by tempering for a given time at a given temp. or by tempering for a longer time at a lower temp. C. Barus and V. Strouhal found that each tempering temp. corresponds with a maximum tempering effect, which is more quickly reached the higher the temp. At 100°, for instance, the maximum effect was not obtained after one hour, and maintaining the steel two hours more at that temp. had little additional effect; at 200°, the maximum effect was obtained in 10 mins.; and at 300°, in one minute. E. G. de Cariolis and R. J. Cowan studied the heat treatment of metals in atmospheres of oxygen, nitrogen, and carbon monoxide; and E. W. Esslinger, the effect of furnace atmospheres.

J. A. Mathews observed that three pieces of the same hardened steel when kept at 422° for 8, 20, and 40 mins., respectively, gave Brinell's hardness numbers of 425, 390, and 340. In general, the rate of cooling from the tempering temp. is immaterial, but after tempering for troostite the steel is generally quenched; in tempering for sorbite slow cooling may make the metal more fragile under shock, a fault referred to as **temper brittleness** or *blue brittleness* (*q.v.*). The combined carbon of steel may occur as a soln. of carbon or cementite in iron—hardening carbon; and as crystalline cementite—cement carbon. In tempering, the proportion of hardening carbon in martensite decreases and the proportion of cementite increases as the tempering temp. increases. E. Heyn thought that another form exists in hardened eutectoidal steel tempered below 400°, because of the carbon remaining as a residue on treatment with dil. sulphuric acid. F. Osmond regarded the residue in E. Heyn's experiment to be derived from finely-divided cementite which formed below 400° and which is decomposed by acid, whereas the cementite formed above 400° is coarser grained and more resistant to the acid. F. Osmond found more heat is liberated in the dissolution of hardened steel than is the case with unannealed steel —*vide supra*, cold-working; E. Heyn also observed that the heat liberated on tempering hardened steel is a maximum at about 300°; and H. Schottzky, that the evolution of heat when hardened steel is heated in water vapour indicates that some tempering occurs at 100°, and the evolution of heat increases with the proportion of carbon up to about 1·22 per cent., and then decreases. Hardened steel contracts at first when tempered, owing to the precipitation of some carbide, but the contraction is followed by an expansion, owing to the transformation of austenite into more bulky martensite.

Temper brittleness is exhibited mainly by alloy steels, although L. Grenet,[6] R. A. Hayward, F. Rogers, W. M. Carr, and others have reported it to occur with carbon steels. The temper brittleness is revealed by the notched bar or impact test, and not by the slow bending of plain bars or the tensile test. Hence, the stresses applied to the steel have to be localized to produce the brittle type of fracture represented by temper brittleness. The tough state appears when the steels are quenched from their tempering temp., and the brittle state when they are cooled slowly. Specimens subject to the disease that appear tough after water-quenching become brittle when cooled in the furnace. A sample of steel slowly cooled from 650° to

250° gave an impact test of 8 ft.-lbs., and when quenched from that temp. the test was 60 ft.-lbs. L. Grenet said that the embrittling effect is regularly observed with steels containing over 0·2 per cent. of carbon, over 0·2 per cent. manganese, 2 to 4 per cent. nickel, and 0·4 to 1·5 per cent. chromium, and that the effect is less regularly observed with steels containing a lower proportion of carbon. L. Grenet found the susceptibility to temper brittleness of acid open-hearth, electric furnace, and crucible steels to be in the ratio 4·7 : 2·2 : 1. Observations on this subject were also made by H. Brearley, R. H. Greaves and J. A. Jones, and Z. Jeffries. The microstructure shows no perceptible difference between the tough and brittle states in a given steel ; but G. d'Huart observed that the blue brittleness and ageing of steel are attended by a precipitation of cementite; H. P. Philpot, Z. Jeffries, and R. S. Archer hold that the fracture of the brittle steel is intercrystalline ; but W. Rosenhain said that it is practically impossible to recognize where the grain-boundaries are in oil-hardened and tempered nickel-chromium steel ; while W. H. Hatfield said that the fracture is not intercrystalline, but rather along the cleavage planes of the crystal grains ; a number of physical properties has been examined in order to find if any show marked differences between the brittle and the tough states.

R. H. Greaves and J. A. Jones found that the sp. gr. of tough steel was from 0·0004 to 0·0010 less than that of brittle steel, and when the tough steel was reheated to 200° the difference was greatly reduced. The difference due solely to toughness or brittleness is, at the most, one part in 20,000. When the effects of unequal tempering are eliminated they could detect no appreciable difference in Brinell's hardness of the two states. The electrical resistances of the two states were found to be the same within the limits of experimental error. The elastic limit of most steels in the brittle state is about 3 tons per sq. in. higher than the same steels in the quenched or tough condition, but with moderate rates of cooling, or when the tough, quenched steel is subjected to low-temp. annealing, the elastic limits in the two states are equalized. F. Rogers said that the brittle steel is softer than the tough steel, but he did not eliminate the effects of the extra-tempering of the brittle steel. F. Rogers, and R. H. Greaves and J. A. Jones obtained evidence that there may be an absorption of heat on heating and an evolution of heat on cooling through the brittle range. L. Guillet obtained no evidence of a difference in the brittle and tough conditions by observations on the thermal expansion or thermoelectric force. J. F. Kayser found that a steel subject to temper brittleness gave a 40 per cent. increase of magnetic remanence when slowly cooled. The phenomenon was studied by W. T. Griffiths, J. H. G. Monypenny, H. Kikkawa, H. P. Philpot, J. H. S. Dickenson, H. Brearley, L. Grenet, W. H. Hatfield, etc. The general results indicate that physical properties other than the notched bar test do show slight differences between tough and brittle specimens. Thus, J. H. Andrew and H. A. Dickie found the sp. vol. and hardness of tough specimens is rather greater than with brittle specimens ; K. Honda and R. Yamada found that the metal in the brittle stage is rather more magnetic than when in the tough stage. W. T. Griffiths discussed nitrogen as a possible factor in favouring the temper brittleness of steel. J. H. Andrew, G. W. Green, and R. H. Greaves and J. A. Jones noted the favourable effect of phosphorus on temper brittleness ; R. H. Greaves and J. A. Jones observed that manganese favours temper brittleness, and in the presence of phosphorus each element intensifies the action of the other one. R. H. Greaves and J. A. Jones observed that silicon favours temper brittleness ; vanadium has very little influence ; tungsten has no appreciable action ; molybdenum reduces or eliminates temper brittleness.

Z. Jeffries suggested that the phenomenon might be due to the existence of a low-temp. allotropic modification of iron, but there is no confirmatory evidence of this. J. H. S. Dickenson considered that the temper brittleness is connected with some alteration of the amorphous, intercrystalline cement, and is therefore confined to the layer, a few molecules thick, between the grains of sorbito-martensite. The

intercrystalline character of the fracture has not been established—*vide supra*. W. H. Hatfield said that the fracture is transcrystalline.

On quenching from the tempering temp. the material has been trapped in a—from a crystalline standpoint—metastable condition, that is, the atoms would not have had the opportunity of finally attaining their stable positions in the system of the crystals. If, after tempering, the cooling be permitted to take place at a slow rate, resulting in a low impact value, the atoms have had the necessary time and opportunity to take up their stable situations in the crystal. The reason for the difference in manner in which the crack is extended is to be found in the relative facility with which it can travel through the diversely oriented crystals. In a perfect crystal, cleavage planes will offer planes of weakness along which the crack may readily run, whilst in the unstable state, in which the perfection of the arrangement is not attained, it is conceivable that the crack will not travel with the same ease.

R. H. Greaves and J. A. Jones examined the hypothesis that temper brittleness is due to the presence of a chromium oxide in the steel, but did not find it satisfactory ; nor did they agree with the hypothesis proposed by F. Rogers attributing the phenomenon to the presence of carbides. He said :

On heating the steel to the dangerous zone, 450°, there is sufficient mobility of the carbides to fall out of solution whilst the nature of the mixture still remains very intimate, *i.e.* there is no microscopically visible aggregation of the constituents . . . at this stage (with probably a minimum of true solid soln. in existence) there is a minimum toughness, since the material is essentially but a mixture of carbides and solvent intimate enough to have mechanical properties appreciably different from those of the solvent, but lacking the toughness which it would have if infused throughout with a tough low concentration soln. Cooled in any manner from this condition, toughness is not regained, for there is no solubility available to yield control below this temp. Heated to the (usual) higher zone, in which there is a degree of solubility, toughness is produced, provided that the cooling through the danger zone be rapid enough to prevent the dissociation of soln. so formed.

J. H. Andrew and H. A. Dickie assumed that the temper brittleness is caused by the carbides separated on the grain-boundaries along the solubility line below the A_1-arrest, and they demonstrated the presence of boundary carbides in brittle specimens of nickel steel. The theory was advocated by K. Honda and R. Yamada, who showed that the brittle metal is more magnetic than the tough metal, in agreement with the observation that carbide dissolved in ferrite diminishes its magnetizability ; and they also showed that the electrical resistance on a rise of temp. is greater than on a falling temp. owing to the dissolution of carbides. A nickel-chromium steel becomes non-susceptible to temper brittleness when it is free from carbon. The carbides here in question are cementite and a complex iron-chromium carbide ; nickel carbides are probably absent because of their instability, and the nickel is present in solid soln. in the iron. As R. Yamada has shown, with a carbon steel the solubility of cementite below the A_1-point, Fig. 51, varies from 0·04 to zero as the temp. falls to room temp., during which period cementite separates on the boundary of the ferrite grains. Nickel-chromium steel will have a greater solubility than carbon steel for the carbides, and just below the A_1-point this solubility decreases, at first rapidly and then gradually as the temp. falls, until at room temp. the solubility of the carbides will be very small or zero. If the specimen be cooled slowly from 650°, the carbides separate on the boundary of the crystal grains and cause temper brittleness. K. Honda and R. Yamada added :

Fig. 51.— The Solubility of Carbon in Steel (diagrammatic).

The sorbite structure which is obtained by tempering a quenched steel consists of a fine mixture of cementite and ferrite, and has a great resistance against the impact test as compared with the pearlite ; while in a steel quenched, tempered, and slowly cooled the carbides present on the boundaries of the sorbitic grains make the material very brittle, so that the susceptible ratio of impact values in these two specimens becomes very large. If the above view is correct, the sorbitic structure is not always necessary for the susceptibility, and the pearlitic nickel-chromium steel, when quenched from 600° to 650°, should

have a greater impact value than the same steel slowly cooled from the same temp. But here the susceptibility ratio must be much smaller; because the pearlite offers much less resistance than the sorbite to the impact test, while the grain boundary has the same strength as before.

§ 8. The Nomenclature of Iron and Steel

SOCRATES : Why should we dispute about names when we have realities of such importance to consider ?

GLAUCON : Why indeed, when any name will do which expresses the thought of the mind with clearness ?—PLATO.

There is a difficulty in formulating precise definitions for the chief varieties of iron and steel—(i) wrought iron, (ii) steel, (iii) cast iron, and (iv) malleable cast iron. Universally-acceptable definitions of commercial iron and steel have not been devised. The various types have been classed in terms of *structure*—eutectiferous and non-eutectiferous ; *origin*—whether of molten or plastic origin ; *malleability*—whether usefully malleable, like steel, wrought iron, and malleable castings, or not usefully malleable, like cast iron ; *composition*—whether the metal owes its special qualities primarily to carbon or to elements other than carbon. H. M. Howe [1] commenced his discussion with the above quotation from Plato's *Republic*, and the subject has been taken up by many others—*e.g.* H. M. Howe and A. Sauveur,

A. Sauveur, A. Greiner, S. Jordan, E. Stassano, A. Semlitsch, J. W. Langley, C. Barus and V. Strouhal, W. F. Durfee, J. O. Arnold, C. H. Ridsdale, H. le Chatelier, K. Honda, J. A. Mathews, H. Scott, A. L. Holley, F. Prime, W. Metcalf, H. P. Tiemann, E. Schrödter, B. Osann, G. Mars, C. Geiger, E. Williams, V. Deshayes, H. Wedding, O. Thallner, K. Honda, J. Navarro, R. A. Bull, etc. *The Sixth Congress of the International Association for Testing Materials* (New York, 1912) discussed various definitions in the attempt to adopt a uniform nomenclature for iron and steel. There are anomalies in the best schemes yet devised. This is perhaps a necessary consequence when convenience and precision are antagonistic, and when arbitrary lines of demarcation have to be drawn in an ill-defined region where one variety merges into another. There are dictionaries of technical terms in the iron and steel industries by O. Thallner, H. P. Tiemann, A. Tolhausen, and W. Venator and C. Ross.

Iron containing varying percentages of silicon, phosphorus, etc., along with so much carbon that it is not usefully malleable at any temp. is called **cast iron**—*fonte* (French) ; *tackjern* or *gjutjern* (Swedish) ; *Roheisen* (German) if not remelted and *Gusseisen* if remelted ; and *ghisa* (Italian). K. Honda defined cast iron as an iron-carbon alloy with a content of carbon lying between 1·7 and 6·7 per cent. The lower limit represents the maximum solubility of carbon in iron at high temp., and the upper limit the case of pure cementite. Cast iron always contains a considerable proportion of carbon—usually from 2·5 to 4·5 per cent. of carbon—and in most cases an important percentage of silicon. The cast iron of commerce is reduced from the ore, usually in a blast-furnace, in direct contact with solid carbon. It is tapped in a molten state from the furnace. The three chief varieties were indicated by Dud Dudley in 1665 :

The first sort is Gray Iron, the second sort is called Motley Iron, of which one part of the Sowes of Piggs is gray, and the other part is white intermixt ; the third sort is called White Iron ; this is almost as white as Bell Mettle, but in the furnace is least fined, and the most terrestrial.

They are the same to-day : (i) **Grey cast iron**—*fonte grise* (French) ; *grätt tackjern* (Swedish) ; *graues Roheisen* (German) ; and *ghisa grigia* (Italian)—which is relatively soft, and characterized by the presence of sheetlets of graphite, often forming an irregular skeleton ; (ii) **White cast iron**—*fonte blanche* (French) ; *hwitt tackjern* (Swedish) ; *Weisses Roheisen* (German) ; and *ghisa bianca* (Italian)—is extremely hard and brittle. It is characterized by having all or nearly all its carbon in the combined state, and by its consequent lack of graphite. (iii) **Mottled cast iron**—*fonte truitée* (French) ; *halfhwitt* or *halfgrätt tackjern* (Swedish) ; *halbiertes Roheisen* (German) ; *ghisa trotata* (Italian)—is intermediate between grey and white cast iron. Emphasizing the high tensile strength of some modern cast irons—30 kgrms. per sq. mm.—A. Thum and H. Ude said that " cast iron is steel rendered impure by graphite."

Cast iron which has been cast direct from the blast or other furnace into moulds of varying sizes and shapes is called **pig-iron**—*fonte en gueuse* (French); *tackjern* (Swedish); *Gusseisen* or *Roheisen* (German) ; and *ghisa* (Italian). The iron solidifies in the slabs or *pigs* ; the moulds are called *pig-moulds*. The name is also applied loosely to molten cast iron which is about to be cast into pigs, or is in a condition in which it could be easily cast into pigs. Molten cast iron which has been passed into or through a metal mixer is called *mixer-metal*. Castings of cast iron are called *iron castings* ; they are usually made by pouring molten cast iron into moulds of designed shape or form, but other than in the shape of pigs or slabs. The molten cast iron is cast direct from blast-furnace, or from cast iron which has been remelted in a cupola, or other furnace, or in crucibles. *Hæmatite pig-iron* is pig-iron made from hæmatite ores containing so little phosphorus and sulphur that the product can be used directly for the acid Bessemer process. In *cinder pig-irons* a large proportion of tap cinder from the puddling-furnace is added to the blast-furnace charge ; the term *all mine pig-iron* is used to distinguish pig-iron from cinder pig-iron when no source of iron is used other than the ore ; *charcoal irons* are pig-irons made by the use of charcoal as a fuel ; *Swedish iron* is made from the magnetite ores of Sweden ; this iron is usually a charcoal iron of a high degree of purity with respect to sulphur and phosphorus ; and *Cleveland iron*, a phosphoric pig-iron made in North Yorkshire. Pig-iron containing

so little silicon and sulphur that it is suitable for conversion into steel by the basic open-hearth process is sometimes called *basic pig-iron*. This metal contains no more than 1 per cent. silicon. The *Thomasroheisen* of Germany contains less than 0·5 per cent. silicon, and over 1·5 per cent. phosphorus ; and here, also, if the pig-iron for the basic Bessemer or basic open-hearth process has a composition outside these limits, and contains phosphorus, it is called *phosphoric pig-iron*. Similarly *Bessemer pig-iron* is pig-iron with so little phosphorus—say, not over 0·06 per cent. (in the United States 0·1 per cent.) phosphorus or sulphur—that it can be used for conversion into steel by the acid Bessemer process. The red-short metal made by purifying pig-iron in the Bessemer converter, without the subsequent removal of oxygen, is called *blown metal*. Molten cast iron from the blast-furnace before it has solidified is called *hot metal* or *direct metal*. Cast iron which has been freed from most of its silicon and phosphorus by rich ferruginous slags or their equivalent, without removing much of the carbon, so that it remains cast iron, is sometimes called *washed metal*—*fonte épurée* (French) ; *tvättad* (Swedish) ; *entphosphortes Roheisen* (German) ; and *metallo defosforato* (Italian). Cast iron which has had most of its silicon removed in a refinery furnace, but still contains so much carbon that it remains cast iron, is called *refined cast iron*—*fonte mazée* (French) ; *raffineradtjern* (Swedish) ; *gefeintes Eisen* (German) ; and *ghisa affinata* (Italian)—or *plate-iron* ; and cast iron which has had its silicon, and usually also phosphorus, removed in the charcoal hearth, but still contains so much carbon that it remains cast iron, is called *charcoal hearth cast iron*. *Bloomary* or *knobbled charcoal iron* is a high-grade iron used for boiler tubes. It is made by heating high-grade charcoal pig-iron in a charcoal knobbling furnace. The lump of iron is hammered into a bloom, and rolled into sinks. *Bushelled iron* is made by heating in a hearth furnace miscellaneous junk scrap iron, often mixed with iron and steel turnings. The heated metal like a puddled ball is squeezed and rolled. The product is irregular in quality. The comparatively rare *alloy cast irons* owe their special properties to the presence of an element or elements other than carbon—*vide infra*, ferro-alloys.

Iron which has been cast as brittle white cast iron into moulds and afterwards made more or less malleable without remelting is called **malleable cast iron**—*fonte malléable* (French) ; *aduceradtjern* (Swedish) ; *schmiedbares Gusseisen* (German) ; and *pezzi fusi dighisa malleabile* (Italian). The malleabilizing is effected by annealing the metal, usually in close contact with an oxidizing agent. As a result most of the contained carbon is converted from a state of cementite into that of temper graphite, and some is removed by the oxidation process. There are in commerce thus two classes of malleable cast iron : one owes its malleability to a large removal of carbon, and the other to a large removal of carbon from the outer part of the casting, and to the precipitation of most of the remaining carbon in the free or graphitic state. It is added that it is not in accord with good industrial usage to apply the name steel to the product of any of these malleabilizing processes. Malleable cast iron differs from steel (i) in containing more carbon, and (ii) in being cast into a mass which is not initially malleable. Malleable cast iron is not cast iron, but a product of cast iron, and it is distinct from wrought iron and steel, which are also products of cast iron.

The malleable casting has a white core—*white-heart malleable cast iron*—if cooled quickly enough, and if it be annealed at 625°–875°, graphite is precipitated to form *black-heart malleable cast iron*, so called because the fracture shows a black kernel with a steel-like skin. In the white-heart cast iron the steely rim may be regarded as extending to the centre—*vide infra*.

The term **wrought iron**—*fer soudé* (French) ; *smidesjern* (Swedish) ; *Schmiedeisen* or *Stabeisen* (German) ; and *ferro fucinato* or *ferro saldato* (Italian)—is applied to iron which has been produced at a temp. below its own m.p., and has been obtained either direct from iron ore or from cast iron ; wrought iron is obtained as a malleable mass from cast iron by the aggregation of pasty particles without subsequent fusion. It contains so little carbon that it does not usually harden when rapidly cooled, and it is soft and readily malleable within wide limits of temp., and always contains intermingled slag. The term weld-iron for wrought iron is obsolete.

The term **steel**—*acier* (French) ; *stähl* (Swedish) ; *Stahl* (German) ; and *acciaio* (Italian)—is sometimes applied to iron with less than 2·0 per cent. of carbon. The term is also applied to alloys to the left of the point E in the equilibrium diagram, and the term cast iron to alloys to the right of that point. C. J. B. Karsten regarded 2·3 per cent. as the limit between steel and cast iron. The fashionable

definition of steel thus depends on an arbitrarily assigned limit. C. Barus and V. Strouhal tried to obtain a physical definition by defining steel as the iron-carbon alloy for which $\delta \log h$ is a maximum when h denotes the thermoelectric hardness taken in a special sense. This definition is not of practical use. According to J. W. Langley, commercial steels have the following composition :

		C	Si	S	P	Mn	O	gases
Steels	Upper limits	1·50	0·30	0·10	0·10	1·00	(1·20)	little per cent.
	Lower limits	0·30	0·02	0·005	0·01	0·08	traces	traces
Alloy steels	Upper limits	2·25	1·50	0·10	0·30	—	2·0	0·25 per cent.
	Lower limits	1·25	0·50	0·01	0·01	—	2·0	0·25 per cent.

The alloy steels also contain the alloying element—e.g. manganese, tungsten, chromium, nickel, etc. The International Association indicated above recommended applying the term steel to iron, alone or associated with other elements, which has been cast from a molten state, whether it hardens or not on rapid cooling from above its critical range, and, after solidification, is so usefully malleable that within some range of temp. it can be forged or rolled into merchant sections or shapes. The term is also applied to iron which has not been cast from a molten state, and contains sufficient carbon to cause it to harden usefully when rapidly cooled from above its critical range, and is so usefully malleable that within some range of temp. it can be forged or rolled into merchant sections or shapes. Otherwise expressed, there are :

(i) *Steels of plastic origin,* which are defined as iron which has not been cast from a molten state but has been aggregated from paste particles without subsequent fusion. It contains sufficient carbon—say 0·30 per cent. or more—to harden usefully when rapidly cooled from above its critical range, and is so usefully malleable that it can be forged or rolled, within some range of temp., into merchant shapes or sections.

The term *blister steel, cement bar,* or *converted bar* is a steel of plastic origin, made from high-class Swedish iron, or wrought-iron bar which has been subjected to a process of cementation, which process introduces carbon into the iron and usually develops blisters on the surface. The same steel when heated and worked into merchant sizes is also called blister steel. Cemented bar, blister bar, shear steel, and a few other high-carbon steels are the only commercial steels covered by this definition. Formerly blister bars were rolled or hammered at a yellow-heat to form the so-called *plated bars* or *bar steel* ; and springs were made from these bars, which were called *spring steel.* Blister bar or cemented bar which has been broken into suitable lengths, heated, and hammered out to confer some toughness and to flatten down the blisters is called *plated bar.* Steel made by piling and welding plated bars under a thin layer of suitable flux is called *shear steel.* If the welded steel has been drawn down the welded bars under a hammer into a faggot which is forged into merchant sizes, it is known as *single shear steel* ; and if single shear steel has been nicked, bent back on itself, the two parts heated, welded, and again hammered down, the resulting bloom is known as *double shear steel.* The merchant sizes forged from these blooms are also known as shear steel. The term *weld-steel—acier soudé* (French) ; *wällstähl* (Swedish) ; *Schweissstahl* (German) ; and *acciaio soldato* or *acciaio fucinato* (Italian)—is iron with a tensile strength of about 50 kgrms. per sq. mm. when annealed ; it contains some slag, because it is made by welding together pasty particles of metal in a bath of slag, as in puddling—hence called *puddled steel*—and it is not later freed from slag by melting.

(ii) *Steels of liquid origin,* which include iron alone or associated with other elements which has been cast from a molten state, whether it hardens or not on cooling from above its critical range, and after solidification is so usefully malleable that it can be forged or rolled, within some range of temp., into merchant shapes or sections.

The metal so defined is steel, whether it can be hardened or not, whether it contains much or little or even no carbon, and, for that matter, even if it be chemically pure iron. It is sometimes called *ingot metal.* With the exception of the comparatively unimportant steels of plastic origin, all steels of any present-day industrial importance are steels of liquid origin. The so-called *ingot iron* is steel with too little carbon to harden usefully on rapid cooling. The term is used in trade, but it is not considered advisable to use the term otherwise, because it is confusing to call a variety of steel " ingot iron." Steel with enough carbon—say 0·30 per cent. or more—to harden usefully on rapid cooling is called *ingot steel.* Steel made in a crucible is called *crucible steel—acier au creuset* (French) ; *Degelstähl*

(Swedish); *Tiegelflussstahl* (German); and *acciaio al crogiuolo* (Italian)—or *cast steel*— *acier au creuset* (French); *gjutstähl* (Swedish); *Gussstahl* (German); and *acciaio fuso* (Italian). When made in an electric furnace, *electric steel*; when made by the Bessemer process, *Bessemer steel*; when made by the open-hearth process, *open-hearth steel*; when made by a basic process, *basic steel*; and when made by the Bessemer process, *acid steel*. The term *semi-steel* is vaguely employed in the trade for various products near the border between cast iron and steel—*e.g.* low-carbon cast iron made in the air furnace or the cupola by adding steel scraps to the charge. It was discussed by J. E. Hurst. The term has also been applied to malleable castings.

K. Honda defines steel as an iron-carbon alloy with a content of carbon lying between 0·035 and 1·7 per cent. The lower limit is given by the solubility of carbon in iron at ordinary temp., and the upper limit is the maximum solubility of carbon in iron at high temp. The term **carbon steel** is sometimes applied to steel which owes its distinctive properties to carbon as distinct from other elements which it contains; and **alloy steel,** or *special steel*, to steel which owes its distinctive properties to some element or elements other than carbon, or jointly to such other element and carbon. Although some of the alloy steels are but moderately malleable, among the carbon steels industrial usage confines the name steel to products malleable enough to be forged or rolled into merchant shapes. There is no agreement as to the line of demarcation between alloy steels and carbon steels. Some alloy steels gave 1·25 per cent. carbon. The term **ferro-alloys** is applied to iron so rich in some element or elements other than carbon that it is used primarily as a vehicle for introducing the alloying element or elements in the manufacture of iron or steel. The ferro-alloys are not usually usefully malleable, and they usually contain more of the alloying element than is desirable in an alloy steel. A substance may simultaneously be an alloy steel in the machine shop and a ferro-alloy in the steel mill. F. Wever discussed the classification of the ferro-alloys.

§ 9. Cast Iron

A. A. Inostzanzeff [1] reported a specimen of native iron from Vladivostock the composition of which was Fe, 93·87 ; C (combined), 0·33 ; C (free), 2·87 ; Al, 0·16 ; Mn, 0·66 ; Si, 1·55 ; and S, 0·04. The composition is thus identical with many artificial cast irons ; and similar remarks apply to its microscopic structure. There are bands of ferrite, granular cementite, a ground mass of pearlite, and some free graphite. This native cast iron is supposed to have been formed in the sedimentary rocks by the interaction of coal and iron ore induced by heat from an intruded igneous rock.

Excluding the ferro-alloys and the alloy steels, the various kinds of iron and steel form a continuous series ranging from the purest iron to the white cast irons. The series divides itself into two parts—graphitic (grey and mottled cast irons) and non-graphitic (white cast iron) ; for the graphitic cast irons can be regarded
Figs. 52, 53, and 54.—A. Sauveur's Diagrammatic Representation of the Formation of the Constituents of Eutectic, Hypereutectic, and Hypoeutectic Cast Iron during Solidification and Cooling.

as white cast irons more or less graphitized. The purest obtainable electrolytic iron is soft and ductile ferrite, and the hardest white cast iron is in the extreme case mainly hard and brittle cementite. The intermediate series is continuous, so that only arbitrary lines of demarcation are possible. The carbon content of steels may range up to, say, 2·0 or 2·20 per cent., and of cast iron from, say, 2·20 to, say, 6·70 per cent. I. L. Bell said that the limit for the combined carbon in cast iron is 4·30 per cent. ; H. M. Howe reported cast irons with up to 4·82 per cent. of combined carbon. A further arbitrary subdivision of the steels is (i) *low carbon steels* with 0·00 to 0·20 per cent. of carbon ; (ii) *medium carbon steels* with 0·30 to 0·70 per cent. of carbon ; and (iii) *high carbon steels* with 0·80 to 2·20 per cent. of carbon. There is some overlapping, because the proportion of carbon in wrought iron may exceed that in some low carbon steels. Thus, J. Percy reported samples of wrought iron with 0·272 to 0·386 per cent. carbon ; L. Cubillo, a sample with 0·24 per cent. ; H. M. Howe, samples with 0·212 to 0·512 per cent. ; and E. Riley, a sample with 0·171 per cent. On the other hand, some low carbon steels—e.g. tube steel—have 0·06 to 0·0 per cent. of carbon. There is a similar overlapping in the proportion

of carbon in the region between steels and cast iron. Thus, H. M. Howe reported cast irons with about 1·61 per cent. of carbon. W. E. Dennison, and J. L. Francis represented the composition of cast iron by volume. The proximate structure of any member of the series between iron and the **white cast irons** can be approximately determined by a consideration of one of the equilibrium diagrams for the iron-carbon alloys—Figs. 61 to 63. Thus, in percentages :

			Total carbon.	Total pearlite.	Excess ferrite.	Excess cementite.	Primary austenite.	Eutectic.	Eutectic austenite.	Eutectic cementite.	Primary cementite.	Total ferrite.	Total cementite.
Carbon Series	Steels	Hypoeutectoidal	0·20	22	78	0	—	0	0	0	0	97·0	3·0
		Eutectoidal	0·90	100	0	0	100	0	0	0	0	86·5	13·5

		Hypereutectic	6·67	0	0	0	0	0	0	0	100	0·0	100·0

The formation of the different constituents during the solidification and slow cooling of eutectic (ledeburite), hypereutectic, and hypoeutectic cast iron was illustrated by A. Sauveur by diagrams analogous to Figs. 52, 53, and 54, for the case where no graphitization occurs. In all cases, after cooling below the pearlitic transformation at about 700°, the ultimate constituents are ferrite and cementite. Fig. 55 represents the microscopic appearance of white cast iron; the dark areas represent ferrite and the white areas cementite. H. A. Schwartz and A. N. Hird said that during the solidification of molten cast iron, equilibrium is attained when the silicon has all passed into the liquid phase, and austenite free from silicon is able to separate. The whole of the silicon is associated with the eutectic cementite, probably as a silico-cementite. The austenite contains the non-sulphide manganese, and on passing through the

FIG. 55.—Structure of White Cast Iron (F. Popplewell).

A$_1$-arrest the manganese is equally soluble in the ferrite and the eutectoid cementite. About 93 per cent. of the phosphorus is found with the cementite. A. Mittinsky, and B. Osann discussed properties of the eutectic.
FIG. 56.—The Effect of Silicon on the Carbon Content of the Eutectic.
FIG. 57.—The Effect of Silicon on the Temperature of the Eutectic.

F. Wüst and O. Petersen showed that the eutectic composition is lowered from 4·3 to 4 per cent. when a little more than 1 per cent. of silicon is present.

Observations were also made by K. Honda and T. Murakami, J. G. Pearce, H. Pinal, A. Wagner, F. Yamada, A. Sauveur, and W. Gontermann—*vide infra*, iron-silicon alloys. The observed results showing the effect of silicon in lowering the proportion of carbon in the eutectic and in raising the eutectic temp. are summarized in Fig. 57. The general behaviour of silicon-iron alloys is discussed above. E. Maurer represented the constitution of cast iron by the diagram, Fig. 58. E. Maurer and P. Holtzhaussen, D. Hanson, E. Scheil, J. E. Hurst, E. Piwowarsky, L. Piedbœuf, J. Challansonnet, H. Tanimura, A. L. Norbury, R. Kühnel, and F. B. Coyle also studied the subject — *vide infra*, Fig. 212, Vol. XIII, tensile strength. The so-called *pearlitic cast iron* was discussed by K. Emmel, L. E. Gilmore, O. Bauer, A. Diefenthaler, H. J. Young, C. Irresberger, J. E. Hurst, J. E.
FIG. 58.—The Constitution of Cast Iron.

Fletcher, L. Piedbœuf, J. A. Smeaton, H. J. Young, G. Gilles, A. E. M. Smith, G. Meyersberg, A. le Thomas, A. M. Portevin, E. Zimmermann, P. Kleiber, R. Moldenke, E. J. Lowry, K. Emmel, B. Osann, R. T. Rolfe, A. A. Mittinsky, R. P. Lemoine, E. E. Marbaker, F. D. Corbin, M. Lincke, G. Sulzer, A. G. Lambert and F. M. Robbins, A. J. Grindle, H. R. Hiscott, W. West, F. K. Neath, A. Logan, S. G. Werner, A. B. Everest, and C. Sipp.

As pointed out by J. E. Stead, grey cast iron, no matter how grey, in its passage from the commencement of solidification to the cold condition, always commences as white cast iron, and gradually becomes grey during cooling owing to the decomposition of the iron carbide, which has a white fracture. The **graphitization** of the cementite in iron-carbon alloys has previously been discussed in connection with the equilibrium diagram. Graphitization is more likely to occur during and after solidification with increasing difficulty in the following order : (i) proeutectic cementite, (ii) eutectic cementite, (iii) proeutectoidal cementite, and (iv) eutectoidal cementite. In the solidification of hypoeutectic alloys austenite is first formed, and at the eutectic temp. cementite falls out of soln. The high temp. of formation of the eutectic cementite favours its graphitization. As the alloy cools, the austenite rejects proeutectoidal cementite, and its graphitization proceeds more slowly, but the process is favoured by the pre-existing nuclei of graphite from the eutectic cementite. The eutectoidal cementite is graphitized with difficulty because of the low temp. If the graphitization of the proeutectoidal cementite is incomplete, the cast iron will have a hypereutectoidal matrix ; if the graphitization of the proeutectoidal cementite is complete, but that of the eutectoidal cementite incomplete, the cast iron will have a hypoeutectoidal matrix ; and if the graphitization of the proeutectoidal cementite is complete and no eutectoidal cementite is graphitized, the cast iron will have a eutectoidal matrix. Fig. 59 (×250) shows the graphite needles in a cast sample of grey cast iron containing 0·97 per cent. of combined carbon, 3·21 per cent. of graphite, and 2·29 per cent. of silicon. There is a ground mass of almost pure pearlite in which the black needles of graphite are embedded. Fig. 60 (×250) shows another sample of cast iron containing 3·391 per cent. of combined carbon, 2·727 per cent. of graphite, and 2·354 per cent. of silicon. The ground mass of pearlite occurs in rounded cells, the white fields in the diagram represent ferrite, and black needles of graphite are embedded in the ferrite. Both specimens are etched with a soln. of hydrochloric acid in amyl alcohol. The case of the graphitization of eutectic alloys needs no special consideration ; and, in the case of hypereutectic alloys, the proeutectic cementite is particularly liable to graphitization, and kish may be formed — *vide supra*. A. L. Norbury and

L. W. Bolton, J. W. Bolton, and H. Pinsl discussed the form of the graphite which separates from iron—*vide supra*; H. Jungbluth, and E. Maurer, the so-called *black fracture* due to the growth of graphite nuclei in steel subjected to abnormal heat treatment; and J. L. Francis, the volume composition of cast iron.

H. Sawamura observed that when chill-cast white cast iron with about 3·4 per cent. carbon, and about 2 per cent. silicon, is heated at a constant rate in vacuo to the end of graphitization and then quenched in water, the proportions of combined carbon after quenching from different temp. are:

Quenching .	1000°	950°	900°	860°	840°	800°
Comb. carbon	0·30	0·21	0·10	0·06	0·02	0·02 per cent.

M. Hamasumi observed that the strength of cast iron increases with the velocity of cooling owing to the more uniform distribution of the curved plates of graphite.

P. D. Merica and L. J. Gurevich found that (i) the greater the carbon content, the narrower the zone of complete graphitization; (ii) more graphite was found in a specimen cooled from 1000° than when cooled from 1100°, and this is taken to mean that the graphite separated from solid soln. on cooling when its nuclei
FIGS. 59 and 60.—Grey Cast Iron containing Needles or Plates of Graphite.

were already present; and (iii) that only 0·2 per cent. of combined carbon was found in some slowly cooled specimens, and this was taken to indicate that the graphite was formed from pearlite at temp. directly below that of its formation, or else the graphite eutectoid occurs at lower values than is generally supposed. R. S. Archer showed that graphitization can be initiated and completed below the A_1-arrest, and that complete graphitization is possible only at or below a point close to or identical with the A_1-arrest. A. Phillips and E. S. Davenport also suggested that temper carbon is derived from areas of solid soln., not from massive cementite; and they found that the areas of temper carbon produced at lower temp. were more compact and sharply outlined than when produced at higher temp. H. A. Schwartz and co-workers assumed that a stable solid soln. of graphite is formed, which they called boydenite—*vide supra*—and the separation of graphite about graphite nuclei may begin at 900° to 1000°. C. J. McNamara and C. H. Lorig thought that the continued slow cooling below the critical point is not necessary for graphitization. The chemistry of cast iron was studied by A. H. Hiorns, L. Houghton, and E. Adamson; and the effect of the melting conditions on the microstructure and mechanical strength, as well as on the distribution of carbon and silicon, by A. L. Norbury and E. Morgan. As a result of the observations of O. Ruff, H. Hanemann, and H. P. Tiemann, H. M. Howe raised the question whether in the absence of manganese and maybe certain other impurities it is possible to

obtain hypereutectic iron, that is, white cast iron containing more than 4·30 per cent. of combined carbon.

O. von Keil found that when the m.p. and f.p. of cast iron are both low, say 1145°, the iron solidifies as white iron, but if both the m.p. and f.p. are high, needle-like graphite is formed ; and if the m.p. is high and the f.p. low, graphite is formed in a finely-dispersed condition. The needle-like graphite separates directly from the fused mass, and the finely-dispersed graphite separates from the decomposition of a metastable solid. Pig-iron separates first as white iron, then, with a high carbon content, the ledeburite first formed decomposes rapidly, with the separation of fine graphite, but in the neighbourhood of the eutectic composition needle-like graphite separates from the liquid phase owing to the retardation of the cooling, For iron of a given composition there is a critical rate of cooling, above which the metal freezes in the metastable state, and below which needle-like graphite separates from the liquid. Overheating reduces the critical rate of cooling to a low value, so that even after slow cooling the metal solidifies in the metastable state. Repeated melting the overheated metal does not cause it to revert to the normal state. As indicated in connection with the equilibrium diagram of the iron-carbon alloys, if cementite be regarded as a metastable phase, there are two equilibrium diagrams, one with cementite and one with graphite. As shown by L. Forquignon, in 1881, the hard iron carbide or cementite is metastable at an elevated temp., and is liable to dissociate. O. Ruff, for instance, estimated that the time required to graphitize half the cementite is decreased by half for every 10° rise of temp. just below 1135°, being 16 secs. at 1105°, 8 secs. at 1115°, and 2 secs. at 1135°. The fact is also evidenced by the slighter graphitization of steel than of cast iron, and of hypoeutectic than hypereutectic cast iron. In both these cases graphitization is favoured by the higher temp. of solidification—*vide infra*. The higher the temp. at which cementite is formed, the more readily will it dissociate into graphite : $Fe_3C=3Fe+C_{graphite}$. The simultaneous production of ferrite and graphite is illustrated microscopically by the frequent juxtaposition of these products—*e.g.* Fig. 64. It will be observed that the low sp. gr. of graphite in comparison with the cementite and ferrite is such that the sectional area of the ferrite from the parent cementite should be about four times that of its twin brother graphite. E. H. Saniter found that when cementite is heated to 800° and slowly cooled, it yields 0·40 per cent. of graphite ; when heated to 1000° and chilled, 0·56 per cent. ; when heated to 1000° and slowly cooled, 2·45 per cent. ; and when fused at 1400° and slowly cooled, 3·05 per cent. F. Mylius and co-workers also observed the decomposition of cementite when fused. A. Lodin pointed out that the dissociation of cementite is accompanied by an expansion, so that the formation of cementite will be favoured by compression such as is exercised by the outer zones on the internal zones in cases of rapid cooling ; and from this point of view slow cooling would thus favour the dissociation of the cementite. W. H. Hatfield added that in cast iron the free cementite is broken up into free carbon and free iron between 800° and 900° ; and that the carbide resulting from the resolution of the hardenite decomposes between 650° and 700°, *i.e.* immediately after or during the hardenite→pearlite change. K. Honda and T. Murakami concluded that graphite in fine cast iron is produced by the decomposition of cementite during cooling, and that graphitization is an indirect process. H. P. Evans and A. Hayes inferred that below 700° and above 850° cementite is metastable in iron-carbon alloys ; and H. A. Schwartz added that as the stable A_3-point in these alloys approaches the A_2-point, the concentration of the element promoting graphitization decreases, and he concluded that the stable A_3-point is below the metastable A_3-point. The subject was discussed by I. R. Valentine, H. Nishimura, H. R. Pitt, A. le Thomas, E. Schülz, and A. M. Portevin and P. Chévenard. A. Allison considered that sulphide inclusions in cast iron served as nuclei for the precipitation of graphite. C. J. McNamara and C. H. Lorig, and H. Sawamura made analogous observations; while L. Northcott found that the free carbon liberated above 1000° tends to become flaky, and if

below 1000° it tends to take on the typical rounded form of annealing or tender carbon. The more compact the granules of carbon, the greater the malleability of the casting. The slower the rate of cooling, the greater the graphitization. This is exemplified by comparing the smaller proportion of graphite in the exterior of chilled castings of grey cast iron with that in the interior. J. E. Fletcher studied the structural relation between the original pig-iron and the derived cast iron, wrought iron, malleable iron, or steel; and W. Bruch, the isotropy of cast iron.

A. Achenbach, E. Adamson, A. Allison, J. H. Andrews, R. S. Archer, P. Bardenheuer and co-workers, O. Bauer, H. H. Beeny, P. F. Blackwood, J. W. Bolton, G. Charpy, E. J. Cook, F. Diepschlag, J. W. Donaldson, E. Dübi, Y. A. Dyer, F. Erbreich, H. P. Evans and A. Hayes, A. B. Everest, H. Field, J. E. Fletcher, W. Gahl, K. Glinz, P. Goerens, P. Goerens and N. Gütowsky, C. Gresty, F. Grotts, M. Hamasumi, H. Hanemann, W. H. Hatfield, A. Hayes and co-workers, W. Heike and G. May, N. Hekker, E. Heyn, J. A. Holden, P. Holtzhaussen, K. Honda and T. Murakami, J. E. Hurst, J. E. Johnson, T. Kase, O. von Keil, O. von Keil and R. Mitsche, R. R. Kennedy and G. J. Oswald, K. von Kerpely, E. Kirk, C. Kluijtmans, O. Kröhnke, R. Kühnel, R. Kühnel and E. Nesemann, F. C. A. H. Lantsberry, J. A. Leffler, D. M. Levy, A. McCance, G. May, P. D. Merica and L. J. Gurevich, W. J. Merten, A. Merz and H. Schuster, E. Meyer, J. W. Miller, R. Moldenke, E. Namba, F. K. Neath, G. Neumann, L. Northcott, B. Osann, J. G. Pearce, T. F. Pearson, B. H. Pinsel, H. R. Pitt, E. Piwowarsky, A. M. Portevin and co-workers, O. W. Porter, H. S. Rawdon and S. Epstein, R. T. Rolfe, P. Ropsy, E. L. Roth, F. W. Rowe, E. Scheil, R. Schmitt, E. Schülz, H. A. Schwartz and co-workers, J. Seigle, J. Shaw, F. T. Sisco, O. Smalley, A. Stadeler, B. Stoughton, H. Tanimura, A. le Thomas, H. P. Tiemann, A. C. Timmins, E. Touceda, T. Turner, G. B. Upton, W. R. Webster, O. Wedemeyer, T. D. West, F. White and R. S. Archer, F. White and H. E. Gladhill, F. Wüst and co-workers, F. Wüst and E. Leuenberger, and E. Zimmermann have studied the microstructure, texture, properties, and the progress of the graphitization of cast iron, etc., with time.

P. Bardenheuer and co-workers, and G. Neumann found that the form and degree of fineness of the graphite are the dominant factors in determining the tensile strength, bending strength, and resistance to shock. The results of these investigations show that the graphitizing reaction is not an erratic phenomenon, but it occurs through the operation of definite natural laws, but the physical constants involved are functions of so many variables that their application is distinctly complex. H. A. Schwartz found that the graphitization curves are all alike when plotted so as to show the graphite formation as a percentage of the possible total at different intervals of the time required to complete half the total reaction. Graphitization proceeds by an increase in the size rather than in the number of carbon nodules. The rate of graphitization is determined by the rate of migration of carbon, in some form, through solid soln. or through ferrite. Either the form in which carbon migrates is always the same, or carbon in all its forms migrates in iron at the same rate. Equal increments in temp. multiply the rate of graphitization by equal amounts. In the initial stages of graphitization the speed is the same above and below the A_1-arrest; and the temp. coeff. of the reaction is of the same order of magnitude. There is no perceptible discontinuity in the speed of graphitization at the critical temp. There is no reason to assume that graphitization does not progress at all temp., no matter how low. P. Chevenard studied the volume changes which occur during graphitization. B. W. Winder found that graphite is formed during the rolling at a dull red-heat of steel with over 0·90 per cent. of carbon; and A. Ledebur said that hammering produces a similar result.

K. Tawara and G. Asahara consider that carbon exists as cementite in molten iron-carbon alloys, and that there is some dissociation, though possibly a small proportion, of the cementite in the soln. into carbon and iron. The free carbon atom may serve as nuclei for the graphitization when the conditions are favourable. When an alloy containing over 2 per cent. and less than 4·3 per cent. of carbon is allowed to cool sufficiently slowly, the primary austenite crystallizes out along the liquidus AB, Fig. 67, and the mother-liquor reaches the eutectic composition B.

At this point, when the cooling is sufficiently slow to maintain the equilibrium, since there are a number of the nuclei already present, graphite will crystallize together with austenite, forming the eutectic. As a general rule the deposition of the dissociated carbon from the molten system will bring about a further dissociation of the molten cementite, in order to re-establish equilibrium. This process is repeated and graphite crystals are developed. On the other hand, the residual molten alloy is diluted all the time by the ferrite, which is the contemporaneous product of the dissociation, and finally it will attain the composition A, which corresponds with that of sat. austenite having 2 per cent. carbon. Consequently, in the final state, there is a eutectic of graphite and sat. austenite, and the whole regulus consists only of graphite and austenite, the latter, of course, resolving into pearlite and needle-shaped cementite when cooled. If the favourable conditions for the solidification of this eutectic of graphite and austenite cease—for example, if the rate of the cooling of the melt becomes greater over a certain range—that process will no longer take place, and cementite will crystallize out of the molten alloy. The separation of cementite at the point B does not represent a true equilibrium; it is a transitional and metastable condition. When the solidification of the alloy is not retarded sufficiently until the whole becomes solid, mottled cast iron will be obtained—*vide supra*.

H. A. Schwartz and co-workers assumed that the solid soln. of carbon in iron, boydenite, is a different phase from austenite, the solid soln. of cementite in iron—*vide supra*; and they explain graphitization as follows:

The process is initiated by the separation of a graphite nucleus, possibly due to carbon precipitated out by some local conversion of austenite into boydenite and excess carbon. The bulk of the solid soln., however, remains austenitic and maintains its carbon concentration by dissolving cementite. More carbon precipitates and more cementite dissolves until the latter is used up.

H. Sawamura said that at a temp. below the A_1-arrest only one process can occur, namely, the decomposition of cementite, but above that temp. the following processes may occur consecutively or concurrently : (i) the cementite is first decomposed to iron and annealing carbon, and then the former absorbs the latter to secure stable equilibrium ; and (ii) the cementite is first dissolved in austenite, and the excess carbon in austenite is precipitated as annealing carbon to secure stable equilibrium. This subject has been previously discussed. H. J. Young described the manufacture of so-called pearlitic cast iron. A. M. Portevin and P. Chevenard, and A. le Thomas discussed the influence of structure on the annealing of cast iron. W. H. Hatfield did not agree with D. M. Levy's statement that the cementite balls up or spheroidizes before dissociation.

As previously indicated, the graphitization of cementite is favoured by the presence of *silicon*. This was noticed by G. Charpy and L. Grenet, H. Sawamura, F. Wüst and P. Schlösser, A. Hayes and H. E. Flanders, D. Hanson, E. Piwowarsky, A. M. Portevin and P. Chevenard, J. H. Küster and C. Pfannenschmidt, F. Roll, G. M. Thrasher, C. James, A. Allinson, D. G. Anderson and G. R. Bessmer, G. Takahashi, A. L. Norbury and E. Morgan, G. P. Royston, and A. Lissner. K. Honda and T. Murakami explained the favourable influence by assuming that (i) a non-magnetic, unstable silicocarbide is formed ; (ii) silicon diminishes the solubility of carbon in austenite ; and (iii) silicon raises the eutectic and eutectoidal temp. H. A. Schwartz found that equal increments of silicon multiply the rate of graphitization by equal amounts ; and the presence of silicon decreases the temp. coeff. of the speed of graphitization; this has not yet been determined, but it approximates to the rule that the logarithm of the temp. coeff. is a linear function of the concentration of the silicon. T. F. Pearson observed that with iron containing 2·5 per cent. of carbon, over 0·75 per cent. of silicon must be present to produce complete graphitization. The effect of silicon has been discussed in connection with Figs. 61 to 63, and also in connection with the silicon-iron alloys. T. F. Pearson represented the effect of silicon on the graphitization in

vacuo by Figs. 61 to 63; and the effect of oxygen was to shift the phase fields more to the right of the temperature axis. E. Piwowarsky, and H. Sawamura found that *titanium* also favours graphitization. The favourable action of *aluminium* on graphitization was observed by W. J. Keep, P. Longmuir, F. Roll, E. Piwowarsky, T. W. Hogg, G. Melland and H. W. Waldron, and H. Sawamura.

The effects of *sulphur* and *manganese* under most conditions are to hinder the formation of graphite. The retarding influence of sulphur and manganese on the graphitization of cast iron was discussed by E. R. Taylor, W. Heike and G. May, B. Osann, E. Leuenberger, F. Roll, A. Hayes and H. E. Flanders, W. P. Putman, O. von Keil and R. Mitsche, F. Wüst, A. L. Norbury, F. Wüst and P. Schlösser, D. M. Levy, R. T. Rolfe, W. H. Hatfield, and H. Sawamura—*vide infra*, iron and sulphur compounds. H. P. Tiemann found that with the proportion of silicon very low, or with proportions of sulphur or manganese proportionally high, graphitization is relatively slow even at 1050°. G. Charpy and A. Cornu-Thenard observed that with 0·14 to 0·40 per cent. of carbon no graphite is formed in the presence of 2·20 per cent. of silicon, but with 4 per cent. of silicon graphitization is complete in 3 hrs. at 800°, and nearly complete in an hour. A. Lissner found that the cementite in white cast iron with 0·4 per cent. of silicon and 0·15 per cent. of sulphur commenced to decompose at 765°, and, at the decomposition temp., rose with increasing proportions of sulphur until it attained 1020° with 1·24 per cent. of
FIGS. 61, 62, 63.—The Effect of Silicon on the Graphitization of Iron-Carbon Alloys.

sulphur. F. Wüst and P. Schlösser said that up to 0·5 per cent. of manganese is indifferent, and F. Wüst and H. Meissner, that its retarding effect does not appear until 2·5 per cent. is present; and H. Sawamura, that the retardation appears when over 1 per cent. has been added. The retarding influence of manganese is attributed to the formation of exothermic Mn_3C, which is more stable than Fe_3C. C. Benedicks, and H. M. Howe discussed the re-solution of the graphite by the austenite as the temp. rises to 900°, and its subsequent reprecipitation on cooling. W. H. Hatfield concluded from his observations on the effects of silicon, sulphur, and manganese on the carbide in cast iron: (i) the silicon is not uniformly distributed through the cast iron, but that the carbide, while not containing so much silicon as the matrix, still contains appreciable quantities; (ii) the manganese is in combination with the carbide to the exclusion of the silicon; and (iii) the proportion of silicon in the carbide is low with high sulphur irons, and the sulphur is in some way responsible for the comparative absence of silicon. T. F. Pearson observed that in the presence of 0·03 to 0·04 per cent. of sulphur complete graphitization was prevented in cast iron with approximately 3·5 per cent. of carbon. E. F. Diepschlag and L. Treuheit studied the effect of lime and of alumina in the slag.

L. Guillet, W. H. Hatfield, M. Waehlert, O. Bauer and co-workers, G. Takahashi, A. B. Everest, E. Piwowarsky and K. Ebbefeld, F. Roll, H. Sawamura, and J. Challansonnet found that *nickel* favours graphitization; H. A. Schwartz, that

nickel hinders the work of silicon as an accelerator of graphitization; and G. Brodsky, that nickel gives castings free from blow-holes and sponginess. O. Bauer and H. Sieglerschmidt, W. Lipin, and M. Hamasumi said that copper is indifferent, but H. Sawamura, and F. Roll found that up to 2 per cent. favours graphitization; O. Bauer and E. Piwowarsky said that *cobalt* is unfavourable, but H. Sawamura said that the effect is favourable though feeble. E. Piwowarsky, and H. Sawamura found that *gold* and *platinum* favour graphitization; and T. F. Jennings, H. Sawamura, and F. Roll, that *chromium, molybdenum* and *tungsten* hinder graphitization. W. H. Hatfield, J. E. Hurst, F. Roll, E. Piwowarsky, and J. Challansonnet, said that *vanadium* hinders graphitization; and P. Oberhoffer doubted this; but H. Sawamura showed that the unfavourable effect is very marked. J. E. Hurst discussed the effect of *titanium*. J. E. Stead, F. Wüst, and P. Goerens and O. Dobbelstein found that *phosphorus* prevents combined carbon existing in forms other than cementite. F. Wüst and P. Schlösser said that up to about 0·5 per cent. of phosphorus has no appreciable effect on graphitization; while M. Hamasumi, F. Roll, and H. Sawamura said that it favours graphitization. The subject was discussed by O. von Keil and R. Mitsche.
FIG. 64.—Relation of the Beginning Temperature of Graphitization to the Proportion of added Element.
FIG. 65.—The Relation between the Proportion of Combined Carbon in the Annealed Alloys and the Proportion of Added Element.

F. Roll said that vanadium, chromium, and manganese preserve the carbide; cobalt, nickel, copper, and zinc decompose the carbide; tungsten, uranium, and lead favour the formation of graphite; whilst tin produces grey cast iron, and molybdenum, boron, aluminium, silicon, germanium, phosphorus, oxygen, and sulphur partly preserve and partly decompose the carbide. D. Saito and K. Nishihara found that manganese favours graphitization.

H. Sawamura summarized his results in Fig. 64, representing the effect of different proportions of the elements on the temp. at which graphitization begins, and in Fig. 65 representing the percentage amount of combined carbon in the annealed alloy with different proportions of the added element. H. Sawamura showed that the elements which favour the graphitization of white cast iron are in the order of their decreasing strength Si, Al, (Ti), Ni, Cu, Co, and P. Platinum and gold also favour the action, while the elements which hinder graphitization in the order of increasing strength are W, Mo, V, Cr, and S. Most of the elements which favour graphitization crystallize in a face-centred, cubic lattice, and most of those which hinder graphitization crystallize in a body-centred, cubic lattice. He showed that most of the elements which favour the graphitization of cast iron have a limit in their effect on the starting temp. for the graphitization of white cast iron.

White cast irons having a high content of some elements (*e.g.* Si, Al, Ti, P) begin to graphitize at temp. lower than their Ac_1. The stability of the cementite in the cast irons with silicon or aluminium changes with the content of carbon and the added element, and the cementite in some of the alloys directly decomposes at temp. lower than their Ac_1 by annealing. These facts probably hold in other cases. In white cast iron alloyed with some elements a part or all of the carbon may exist in a combined form different from cementite. The stability of the combination, of course, influences the graphitization of the mother white cast iron, *e.g.* alloys with silicon or aluminium. In white cast irons which rapidly graphitize by annealing— that is, alloys containing a high proportion of silicon, aluminium, titanium, or nickel—the form of the temper-carbon produced is always governed by the form of the cementite and in most cases is flaky. Both the number of particles and the grain-size of the temper-carbon are also governed by those of the cementite in the alloys. In white cast iron which slowly graphitizes by annealing—that is, alloys with a low proportion of silicon, aluminium, titanium, or nickel; or containing cobalt, copper, phosphorus, molybdenum, or other elements having an unfavourable effect on graphitization—the form of the temper-carbon is different from that of the cementite and is always nodular. Generally speaking, the grain-size of the nodular temper-carbon is far larger and the number of the grains is far smaller than expected from the structure of the alloys in the cast state. The mechanism of the formation of temper-carbon is of the same nature as that of the formation of graphite in cast iron during cooling, and consequently the effect of the elements on the formation of graphite in cast iron can be approximately inferred.

By annealing specimens in atmospheres of carbon monoxide and dioxide, under press., at 927°, A. Hayes and G. C. Scott showed that the rate of absorption of free carbide was increased nearly 100 per cent. ; and at the critical range graphitization was inhibited by the gas mixture. H. Sawamura studied the effect of gases on the graphitization of cast iron, and found that the action is retarded by hydrogen, ammonia, and methane ; carbon monoxide and dioxide have a moderate retarding effect ; and nitrogen, oxygen, and air are indifferent. The action with malleable cast iron is rapid in carbon dioxide, and it is retarded by hydrogen, ammonia, and methane. T. F. Pearson observed that whilst sulphur and oxygen separately tend to inhibit graphitization, together they counterbalance one another to some extent. The general effect of oxygen is to push the phase fields to the right of the temp. axis.

H. Sawamura [2] discussed the effect of *the rate of solidification* of white cast iron containing silicon, and found that the effect on the graphitization is remarkable. A given white cast iron graphitizes more easily the faster it has been solidified, and the increase in vol. due to complete graphitization is far greater with the rapidly solidified metal than it is with the same metal more slowly solidified. The effect of *the temperature of casting* on the properties of the metal has been examined. Apart from the regular mechanical defects in castings produced at too low or too high a temp., the mechanical properties of cast iron or steel are to some extent determined by the initial temp. at which the molten metal enters the mould. T. Turner observed that cast iron is perhaps not so sensitive to the effect of variations due to pouring temp. as are some other metals, and herein lies one of its great advantages, in that castings are not so readily spoiled by inattention. R. A. Hadfield said that steel cast too hot has a peculiar crystalline fracture, which disappears on reheating, but the metal is never quite satisfactory ; and if the metal is cast too cold, the metal is unsatisfactory in mill and forge. J. O. Arnold also found a difference in the mechanical properties of steel which had been cast at different temp. G. M. Thrasher found that by varying the pouring temp. it is possible to pour a test of mottled cast iron and of grey cast iron from the same ladle of iron. P. Oberhoffer and H. Stein considered 1240° to be the optimum temp. for casting ordinary iron from a cupola. G. Hailstone obtained the best results between 1428° and 1386°. A. McWilliam found that with special crucible steels the metal

should be cast as cold as possible consistent with the last drop being liquid and falling into a thoroughly liquid bath. A. le Thomas discussed the effect of the speed of cooling and said that the strength of the metal depends on a kind of heredity, *i.e.* on the structure imposed on the metal during solidification. Observations were made by F. Beitter, H. H. Campbell, A. Sauveur, E. Piwowarsky, C. Schreiber and H. Menking, J. E. Hurst, A. McCance, H. A. Schwartz, E. J. Lowry, A. Ledebur, W. J. Keep, E. Deny, E. F. Dürre, J. Kollmann, T. Turner, F. Busse, F. J. Cook, K. Honda and T. Murakami, H. Hanemann, E. Meyer, T. Klingenstein, P. Bardenheuer and co-workers, H. M. Howe, and R. Hohage.

W. H. Hatfield observed that the temp. of casting influences the proportion of combined and free carbon. The higher the casting temp., the greater the pro-
FIG. 66.—The Dissolution of Graphite in Molten Iron.

portion of combined carbon. G. Hailstone also said that as the casting temp. falls, the proportion of combined carbon is reduced. P. Bardenheuer and K. L. Zeyen also observed that the higher the temp. at which cast iron is heated in the molten state, the smaller is the amount of graphite which separates on cooling. F. Sauerwald and A. Koreny found that the rate of dissolution of graphite in cast iron at 1255° and 1350° follows the regular law, being proportional to the degree of saturation of the molten metal, the form of the graphite particles, the temp., and the time of contact. The amount of graphite dissolved in a given time increases rapidly with temp., and that dissolved at a given temp. at first increases rapidly with time and then proceeds more slowly and the results furnish a hyperbolic curve.

G. Charpy, speaking generally, observed that the size of the crystals varies with the speed of solidification ; the slower the rate of solidification, the more the crystals are developed. Generally the size of the grain is increased by casting at a high temp. and in warm moulds, or in cooling slowly. On pouring at a low temp., in metallic moulds so as to ensure rapid cooling, a fine crystallization will result. As the conditions of pouring modify equally the mechanical properties corresponding with a given composition, one can form an idea of the properties of a cast metal from the size of the grain, as has been done by A. Sauveur in the case of steel. P. Longmuir found that in general bars of cast iron are dry and open in fracture with a high casting temp. ; close and uniform with a medium casting temp. ; and open with a low casting temp. Bars cast at a medium temp. were sounder than those cast at a high or at a low temp. The sp. gr. of cast iron is, as a rule, increased by lowering the temp. of casting. A sample of cast iron with 3·35 per cent. of combined carbon, cast at 1440° and 1299° respectively, gave tensile strengths of 9·4 and 12·1 tons per sq. in. Again, a steel with 0·52 per cent. combined carbon, 3·4 graphite, 1·78 Si, 0·28 Mn, 0·04 S, and 0·28 P, when cast at 1400°, 1350°, and 1245° gave tensile strengths of 9·7, 14·1, and 10·6 tons per sq. in. respectively. In general, with both cast iron and steel, the tensile strengths, elastic limits, and elongations were better when cast at the intermediate temp., and this also applied when the cast metal was heated to 1000° and slowly cooled, or annealed, or quenched from 940°. E. Piwowarsky, and E. Schüz discussed the annealing of cast iron. W. H. Hatfield, however, observed that there is a great variation in the strength of cast iron of the same composition and that the variation does not appear to follow any recognizable rule with regard to the temp. of the casting operations ; that a difference in mechanical tests is generally accompanied by a difference of microstructure ; and that the inequalities of the metal can be annulled by a judicious heat treatment; that is, under certain conditions, the irregularity need not persist after heat treatment.

C. Benedicks and H. Löfquist thus described the constitution of grey cast iron. Structurally, grey cast iron contains (i) A ground-mass of iron, generally containing in soln. a considerable amount of silicon (silico-ferrite) and also some manganese. (ii) Graphite, occurring partly in the form of large lamellæ precipitated during solidification, partly as smaller particles precipitated in the solid state (temper carbon); its total amount is generally about 3 per cent. (iii) A certain amount of combined carbon, occurring generally as pearlite. If the manganese is high and the silicon low, the carbon may also be present as free cementite, formed during the solidification. Further, impurities occur, such as phosphorus and sulphur. The most characteristic feature of the cast iron may be said to be its high degree of heterogeneity, due to the soft graphite lamellæ. Their considerable quantity and extent cause a low tensile strength, unusual for metallic materials ; as a matter of fact, the graphite lamellæ act as notches, inducing cracks.

W. H. Hatfield regarded grey cast iron as a matrix of ferrite or of silicoferrite strengthened by pearlite which is cut up and weakened by numerous plates of graphite and possibly also of phosphides. If the proportion of silicon is low, or if other favourable conditions exist, a cementite network is formed, and this strengthens the material under compression. **Annealing** relieves the internal strains set up during the solidification of the iron, and it also softens the casting. A short annealing of grey cast iron between 750° and 800° breaks down the cementite network to form graphite and ferrite. *Mutatis mutandis*, the grey cast irons, indeed, are structurally similar to carbon steels, but the cast iron is weakened by the presence of the graphite flakes, just as would be the case if the steel were weakened by a number of indiscriminate cracks. Thus, P. Longmuir found that grey cast iron with 0·52 per cent. of combined carbon and 3·4 per cent. of graphitic carbon, cast at 1350°, had a tensile strength of 14·1 tons per sq. in., and when annealed at 940° and cooled slowly, the tensile strength fell to 9·9, and when cooled by quenching, to 3·0 tons per sq. in. W. H. Hatfield observed that the weakening of the metal by annealing is connected with the way the graphite segregates during the heat treatment. A. Campion and J. W. Donaldson found that the strength is improved by heat treatment up to 400°, and is not seriously modified up to 700°. F. Graziani, R. T. Rolfe, and W. H. Hatfield observed that annealing below 500° reduces the initial strains set up during the solidification of the metal, without at the same time materially affecting the mechanical strength ; and J. E. Hurst observed that the combined carbon is not quite stable at 575° to 600°, for annealing at these temp. generally reduces the hardness and tensile strength. The weakening or embrittling action produced by the graphitization of cast iron was also confirmed by the work of W. J. Keep, W. A. Jenkins, G. Jüngst, G. R. Johnson, E. Gridley, G. L. Norris, W. P. Putman, S. B. Chadsey, B. Osann, etc. The softening of grey cast iron is affected by annealing for 6 to 12 hrs. at 650°, or by cooling slowly from 800° to 900°. H. Sawamura represented the speed of graphitization by $V=at^n$, or $V=ak^n\theta^n$, where a and k denote constants, and V denotes the speed, t the time, and θ the temp.; while n is probably a constant and independent of the chemical composition, or else is equal to 2, and a variable. It was observed that the speed of solidification of cast irons with silicon as an impurity is independent of n and a, but the speed of graphitization at the eutectic temp. of quickly solidified cast iron is greater than that of slowly solidified cast iron of the same composition. The amount of cementite remaining undecomposed in cast iron depends on the product of the speed of graphitization of cast iron at its eutectic temp. and the time occupied in cooling from the eutectic temp. to the temp. at which graphitization begins. Hence, the degree of graphitization of white cast iron greatly depends on the temp. at which graphitization begins and the speed of graphitization. H. A. Schwartz and co-workers also discussed the mechanism of the reaction. There is nothing to show that graphitization does not occur very slowly at low temp. The curves furnished an equation which, by extrapolation at 20°, indicated that white cast iron, after the lapse of 20 years, should contain about 0·0001 per cent. of graphite. The thermal coeff. of the reaction indicated that a rise of 20° multiplied the velocity by 1·229. W. Fraenkel and E. Heymann discussed the kinetics of the process of annealing—*vide supra*.

Observations on the annealing and heat treatment of cast iron and steel were reported by E. Piwowarsky, E. Schüz, O. W. Potter, A. Pomp and co-workers, R. Stotz, F. Wüst and E. Leuenberger, E. Leuenberger, H. E. Diller, P. Chevenard, E. Touceda, J. E. Stead, H. R. Stanford, R. A. Hadfield, G. P. Royston, C. James, N. Hekker, V. V. Usoff and N. N. Pustuimikoff, E. H. Putman, G. C. Davis, A. Hayes and co-workers, H. Fay and S. Badlam, Y. Watanabe, etc. G. Charpy and L. Grenet summarized their observations as follows : (i) free carbon separates at a lower temp. when the proportion of silicon is high ; (ii) the separation of free carbon once begun continues at temp. below those which inhibit the reaction ; (iii) at a constant temp. the separation of carbon is effected progressively more freely as the temp. is lower and the proportion of silicon is less ; (iv) the amount of combined carbon which corresponds with a state of equilibrium at a given temp. diminishes with an increase in the silicon content ; (v) the amount of combined carbon corresponding with a state of equilibrium diminishes as the temp. decreases ; (vi) the structure of the temper-carbon varies with the temp. at which it is produced ; (vii) the precipitation of carbon is more complete in certain regions, and proceeds from various centres ; and (viii) the ultimate stable phases are ferrite and free carbon. A. Hayes and G. C. Scott studied the effect of annealing in an atm. of carbon monoxide and dioxide under press.

According to W. H. Hatfield, a small casting of cast iron is brittle and will not resist shock ; small steel castings cannot be made cheaply because of the comparative difficulty in attaining a sufficiently high temp. to make small castings satisfactorily. Cast iron can be melted with ease and cast into the smallest and most intricate shapes. Hence, the discovery that the annealing of some kinds of iron furnishes a product almost as tough and ductile as wrought iron became of great industrial value. In 1722, R. A. F. de Réaumur softened cast iron and rendered it malleable to a certain extent by exposing it to a high temp. with excess of air while embedded in hæmatite—*safran de Mars* ; he found that the red oxide of iron gave better results than chalk, bone-ash, etc. S. Lucas obtained a patent for a similar process in 1804. About 1732, C. Neumann also noted that :

Cast iron surrounded by animal ashes, and exposed to a fire not sufficient to melt it, becomes in a shorter or longer time, according to the strength of the fire and thickness of the metal, so soft that ornaments or utensils made of it, however hard before, may now be easily cut, filed, embellished, or freed from their superfluities. The gradual changes produced in this process are pretty remarkable.

In 1769, J. Ashton obtained a patent for softening cast iron by the heat of a slow fire ; and in 1783, G. Matthews obtained another patent for softening large castings such as guns, etc., by a similar process ; and J. E. Beauvalet, still another in 1852. The subject is here connected with the decarburization of cast iron—*vide infra*. The product of processes based on that of R. A. F. de Réaumur is sometimes called **European** or **Réaumur's malleable cast iron.** It will be observed that rapid cooling of cast iron favours the formation of cementite at the expense of the graphite, and it also yields the graphite in smaller granules. When the graphite is generated in cast iron at the high temp. of solidification, 1135°, and immediately below, the mobility is great enough to allow the graphite to assemble in long flakes, which break up the continuity of the mass so as seriously to interfere with its mechanical properties. If, however, the graphite be generated at a lower temp., say at 730° for 60 hrs., it forms an impalpable powder filling the interstices between a skeleton of ferrite and pearlite, as shown in Fig. 58. The continuity of the mass in consequence is not so seriously broken. The purpose of **black-heart malleabilizing** is to break up the hard and brittle cementite so as to avoid the development of the graphite during and immediately after solidification, but to induce its formation at about 730°, when it is in a condition to do least harm. The product of this operation is sometimes called **American malleable cast iron** because of its development in American foundries. It is also called **black-heart,** and that produced by

the Réaumur's process **white-heart.** It gives higher mechanical tests than the Réaumur malleable cast iron.

The manufacture of malleable cast iron was discussed by G. A. Ackerlind, E. Adamson, E. Adamson and J. E. Fletcher, R. D. Allen, J. H. Anderson, P. Bardenheuer, W. R. Bean and co-workers, A. J. Beck, G. A. Blume, E. C. Boehringer, S. Bolland, A. Boussu, O. Brauer, E. Bremer, J. Bronn, C. Busquet, A. Cairnes, E. F. Cone, F. J. Cook, M. Dalifol, R. W. Davenport, G. C. Davis, J. D. Deisher, W. J. Diederichs and H. E. Flanders, H. E. Diller, R. L. Dowell and J. T. Gow, E. F. Dürre, M. Epstein, F. Erbreich, G. A. Evans, W. T. Evans and A. E. Peace, S. J. Felton, H. Field, B. Finney, E. P. Fischer, D. P. Forbes, L. Forquignon, R. Gailly, L. E. Gilmore, N. G. Girschowitsch and E. C. Widin, M. Guedras, A. Harley, W. H. Hatfield, A. Hayes and co-workers, N. Hekker, H. Hemenway, C. C. Hermann, G. Hofer, F. H. Hurren, H. W. Hyde, C. James, A. T. Jeffrey, T. Kikuta, F. R. King, C. Kluijtmans, C. E. Kluijtmans and W. H. W. Proctor, B. Kranz, G. L. Lacher, M. Lamla, E. H. Leasman, M. Leroyer, T. Levoz, O. M. Levy, A. Lissner, T. D. Lynch and W. J. Merten, M. M. Marcus, L. H. Marshall, C. J. McNamara and C. H. Lorig, F. A. Melmoth, A. W. Merrick, R. Moldenke, J. V. Murray, E. Namba, R. Namias, J. B. Nealey, S. S. Nekryti, P. Oberhoffer and J. Welter, P. Oberhoffer and E. Zingg, E. C. Ongley, B. Osann, S. J. Parsons, P. A. Paulson, A. E. Peace, J. P. Pero, J. P. Pero and J. C. Nulsen, A. Phillips and E. S. Davenport, E. Piwowarsky, C. H. Plant, A. L. Pollard, W. H. Poole, E. H. Putman, W. P. Putman, R. N. Richardson, P. Rodigin, G. P. Royston, D. Saito and H. Sawamura, U. Savoia, O. Schliewiensky, W. Schneider, E. Schömann, E. Schüz, H. A. Schwartz, G. R. Shotton and R. G. Hall, R. H. Smith, H. R. Stanford, O. W. Storey, R. Stotz, B. Stoughton, C. L. Sullivan, E. R. Taylor, J. H. Teng, A. le Thomas, G. M. Thrasher, E. Touceda, T. Turner, I. R. Valentine, P. Vidor, A. Wahlberg, H. Wedding, E. C. Wheeler, A. E. White, A. E. White and R. S. Archer, D. Wilkinson, F. Wüst, and F. Wüst and E. Leuenberger. The properties of malleable cast iron were discussed by A. G. Ashcroft, P. Aubie, H. Bornstein, E. Chamberlain, A. T. Child and W. P. Heincken, F. B. Coyle, H. E. Diller, H. Field, M. Gailly, C. H. Gale, L. E. Gilmore, W. H. Hatfield, F. Henfling, G. Hofer, F. H. Hurren, D. H. Ingall and H. Field, E. E. Marbaker, L. H. Marshall, A. Mertens, R. Moldenke, W. J. Molineux, J. V. Murray, E. Namba, A. E. Outerbridge, A. Phillips and E. S. Davenport, J. Piers, H. Pinsl, W. P. Putman, O. Quadrat and J. Koritta, E. Schüz, H. A. Schwartz, E. K. Smith, E. K. Smith and W. Barr, J. K. Smithson, H. R. Stanford, J. E. Stead, R. Stotz, C. L. Sullivan, E. R. Taylor, E. Touceda, E. C. Wheeler, W. Valentin, and I. R. Valentine.

The following are some books and monographs on malleable irons :

H. W. Craver, *Bibliography of Articles on Malleable Cast Iron since 1894*, Pittsburg, 1895 ; *Bull. Brit. Cast Iron Research Assoc.*, 1, 1923 ; W. H. Hatfield, *Cast Iron in the Light of Recent Research*, London, 1912 ; H. M. Howe, *Iron, Steel, and other Alloys*, Boston, 1903 ; *Metallography of Steel and Cast Iron*, New York, 1916 ; R. Moldenke, *The Production of Malleable Castings*, Cleveland, Ohio, 1921 ; S. J. Parsons, *Malleable Cast Iron*, New York, 1919 ; E. Schüz and R. Stotz, *Der Temperguss*, Berlin, 1930 ; H. A. Schwartz, *American Malleable Cast Iron*, Cleveland, U.S.A., 1922 ; T. Turner, *Metallurgy of Iron*, London, 1915.

J. E. Johnson induced a **spheroidization of the graphite** by first bessemerizing the iron at a low temp., and when the iron is remelted with some silicon, the required degree of graphitization is obtained, for the spheroidized characteristic persists during the remelting. J. E. Johnson's idea is that the oxygen introduced during the bessemerizing lowers the temp. of graphitization relatively to that of solidification, so that the rigidity of the mass prevents the graphite spreading out into broad flakes.

In the process employed by R. A. F. de Réaumur[3] for malleabilizing cast iron the iron is embedded in red oxide of iron, so that in addition to the transformation of hard cementite into graphite and soft ferrite, a process of decarburization, or **decarburization** by the oxidation of the carbon, is at work ; and J. J. Berzelius said that when iron rich in carbon is heated in air—*e.g.* in converting cast iron into wrought iron—the air does not come into contact with all the particles, but carbon travels from within outwards until equilibrium is established. This is a reversal of the process of cementation (*q.v.*), in which, according to A. C. Becquerel, the atoms of iron at the surface which have combined with carbon turn half-round, give up their carbon to the iron atoms immediately within, take up another portion at the surface, and so on until the two substances have penetrated one another completely.

At a red-heat the iron is sufficiently soft to allow this rotation of the atoms. A. F. E. Degen admitted that this is possible, though the hypothesis has too much imagination and too little fact to be accepted in detail at the present day. According to A. Ledebur, the decarburization is not confined to the surface of the glowing piece of iron, but it also penetrates to the inmost parts. As long as the heating is sufficiently prolonged and the temp. is high enough a circulation of carbon takes place. When the carbon at the surface of the iron is oxidized, the carbon flows, so to speak, from within outwards, so that the concentration of the carbon in each part approaches uniformity. As soon as one part has a less proportion of carbon than another, the carbon may be imagined as passing from one molecule to another. F. Wüst did not accept the diffusion hypothesis of A. Ledebur, and he said that the process of diffusion can occur where carbon is in soln.; free carbon can in no way travel from mol. to mol. in solid iron. It has been shown above that the successful production of malleable cast iron depends largely upon the precipitation of carbon, so that the malleabilization involves the elimination of the carbon by oxidation and the precipitation of annealing carbon. F. Wüst said :

The oxidation of the annealing carbon can take place not only at the points of contact between the iron oxide and the heated iron, but it also must distribute itself throughout the mass of metal. The carbon, he said, does not move towards the oxidizing agent, but conversely, the oxidizing agent beginning its activity at the surface, gradually penetrates the metal, and in this way reaches the annealing carbon not yet oxidized. Accordingly, the oxidizing agent can only be a gas giving off oxygen, and the iron oxide used to carry on the process of elimination effects only indirectly the conversion of carbon into gas.

F. Wüst showed that the elimination of carbon is confined to the free annealing carbon, since analyses show that only that form of carbon diminishes, while the combined carbon remains constant. The gas which actually effects the elimination is carbon dioxide, for that gas decreases and carbon monoxide increases during the decarburization. The ferric oxide begins to give off oxygen at about 600°, and this oxygen combining with the free annealing carbon produces carbon dioxide; as soon as the oxygen has been used up, the process is kept up by the carbon dioxide, which unites with the annealing carbon to form carbon monoxide; that carbon monoxide then reacts with the iron oxide, reducing it to metallic iron and ferrous oxide, whereby carbon dioxide is again generated. The ratio $CO_2 : CO$ in the gas thus depends upon the proportion of ferric oxide to the cast iron being decarburized. The rise of press. reaches its maximum, temp. constant, when a state of equilibrium is established between the partial press. of the oxygen and the dissociated press. of the iron oxide. If there is a lack of oxygen from the bed of ferric oxide, the carbon dioxide is not regenerated and the proportion of carbon monoxide in the mixture can increase to such an extent that the process of decarburization becomes one of cementation. Under these conditions a microscopic examination of a polished and etched section shows that :

The metal being decarburized has a surface of ferrite, below that is a layer of pearlite, and in the middle is a layer of ferrite and annealing carbon. The band of pearlite is supposed to have been formed by a reversal of the annealing process into a cementation process. The carbon monoxide increases to such an extent that it can neither have an oxidizing action nor remain neutral, but, acting in accord with $3Fe+2CO=Fe_3C+CO_2$, it produces an increase of carbon in the metal, for the iron takes up carbon from the carbon monoxide.

P. Goerens accepted F. Wüst's theory of the process of decarburization; but W. H. Hatfield did not agree with the assumption that carbon must be precipitated from solid soln. before it is oxidized, because the separation of carbon from white cast iron occurs throughout the mass, and hence, in F. Wüst's experiments, if the carbon in the interior is in the combined state, the outer decarburized layer does not contain free carbon. He therefore represented the process of decarburization: $2Fe_3C+2CO_2=6Fe+4CO$; $2CO+O_2=2CO_2$; $2CO_2+2Fe_3C=6Fe+4CO$; and so on; and not as F. Wüst did: $Fe_3C=3Fe+C$; $C+CO_2=2CO$; $2CO+O_2=2CO_2$; $C+CO_2=2CO$; and so on. W. H. Hatfield also said that the surface of the billet

or ingot in any mill or forge has a tendency to be decarburized by furnace gases, and this with steels free from combined carbon; and that at 960°, the temp. employed by F. Wüst, much of the annealing carbon would re-combine with the iron. This is in accord with observations by W. H. Hatfield, R. A. Hadfield, T. Murakami and H. Sekiguchi, J. O. Arnold and A. McWilliam, E. H. Schulz and P. Niemeyer, E. H. Saniter, G. P. Royston, G. Charpy, C. Benedicks, M. Winter and P. B. Crocker, and H. F. Rugan and H. C. H. Carpenter. F. Giolitti, in opposition to F. Wüst, said that in producing malleable iron decarburization does not occur until the carbon of the cementite has separated in the form of temper-carbon, and that the oxidation of the carbon in the interior of cast iron is due exclusively to the penetration of the heated metal by oxidizing gases. Besides the temper-carbon, the carbon dissolved in the iron is oxidized directly; and in addition to the penetration of the heated metal by the oxidizing gases, the dissolved carbon migrates towards the surface of the iron owing to differences of concentration in the inner and outer portions of the metal. W. H. Hatfield thus summarizes his interpretation of the decarburization :

The carbon is eliminated while still in combination with the iron. At the comparatively low temp. of 750° C. this reaction begins to take place between the carbide of iron and the oxidizing medium. The activity of the elimination gradually becomes greater with the increase in temp. until a temp. is reached at which, according to the composition of the iron, the precipitation of annealing carbon takes place, until equilibrium for that temp. is established. Previous to this precipitation the iron consists of a decarburized exterior, with the interior still retaining the original quantity of combined carbon. After precipitation the decarburized exterior is still present, but in the centre there is a composition equal to saturated or slightly supersaturated steel, in which the precipitated temper-carbon is contained. The carbon now in soln. would appear to diffuse outwardly to the skin to replace the already eliminated carbon. As in this manner further combined carbon is removed from the iron, so is the equilibrium maintained by the absorption and soln. of more temper-carbon to fill its place. The effect of a diffusion or absorption of temper-carbon in this manner is shown by the fact that on the completion of the softening of this material considerable quantities of annealing carbon remained.

E. D. Campbell and co-workers, and J. Cischina studied the decarburization of steel by hydrogen; J. V. Emmons, by hydrogen, steam, carbon dioxide, oxygen, and air; and W. E. Jominy, and G. Belloc, by occluded gases. For the decarburization of steel by hydrogen and nitrogen, vide infra, chemical properties of iron. No decarburization occurred below the Ac_1-arrest. It was inferred that the carbon must form a solid soln. with iron to permit of its oxidation, and the depth of oxidation is dependent on the speed of diffusion of the carbon. Steam had the strongest action, then carbon dioxide, and finally air and oxygen. No action at all was observed with hydrogen. J. V. Emmons also noted that steel is decarburized if heated in charcoal at 780°, and H. C. Greenwood obtained a similar result, and also noted a decarburization when the metal is heated in a lead bath containing a little oxide. H. Scott observed that in air there is scarcely any decarburization, owing to the fact that scale formation proceeds at the same rate as decarburization. Heating half an hour at 1060° gives the same depth of decarburization as an hour at 970°, but less ferrite is formed than at the higher temp. E. H. Schulz and P. Niemeyer found that in air no difference was observed with planed, ground, and polished surfaces; for a constant period of time the decarburization is proportional to the temp.; at the same temp. the speed of decarburization is greatest at the beginning of the heating; in a eutectoidal steel incipient decarburization appears after 2 hrs.' heating at 700°; eutectoidal steel decarburizes deepest, and a hypoeutectoidal steel decarburizes deeper than a hypereutectoidal steel below 1000°, but at 1100° the reverse is the case; silicon and tungsten steels show distinct decarburization at 800°, but chromium and manganese steels show no trace of decarburization at 900°; at 1000°, chromium steel showed a decarburization of 0·06 mm.; manganese steel, 0·2 mm.; silicon and carbon steel, 0·3 mm.; and tungsten steel, 0·4 mm.; and at 1100°, decarburization is fastest with chromium steel. Hence tungsten should promote

decarburization, chromium and manganese should reduce it, and silicon should have no influence.

A. Johansson and R. von Seth showed that the main reactions concerned in the carburization and decarburization of iron by mixtures of carbon monoxide and dioxide are $Fe_3C \rightleftharpoons 3Fe+C$ and $2CO \rightleftharpoons C+CO_2$, on the assumption that carbon has a small but definite vap. press. which is constant for a given form of carbon at any assigned temp., but is variable for different modifications of carbon. Let the concentration of carbon dioxide, carbon monoxide, and carbon vapour be respectively denoted by [CO], [CO$_2$], and [C$_3$]; then, for equilibrium, $[CO]^2 = K_3'[CO_2][C_3]$, but since the vap. press. of carbon is constant, $[CO]^2 = K_3[CO_2]$, where K_3', [C$_3$], and K_3 are functions of the temp. only. Let [C$_1$] denote the vap. press. of the carbon of cementite, and [C$_2$] that of the carbon of the solid soln. of carbon in iron, then [C$_2$], unlike [C$_3$], is a function of the concentration of the carbon in solid soln. as well as of the temp. For the reaction $3Fe+2CO \rightleftharpoons CO_2+Fe_3C$, $[CO]^2 = K_1'[C_1][CO_2]$, where $K_1' = K_3'$, the dissociation constant of carbon monoxide, and $[C_1] = [C_2]$. Consequently $K_3'[C_2] = K_1'[C_1] = K_1$, and $[CO]^2 = K_1[CO_2]$. Hence,

$$\frac{K_1}{K_3} = \frac{[C_2]}{[C_3]} \qquad \qquad \qquad \text{. . . . . (1)}$$

or the equilibrium constants of the reactions $3Fe+2CO \rightleftharpoons Fe_3C+CO_2$ and $2CO \rightleftharpoons C+CO_2$ stand in the same relation as the carbon press. of cementite and elementary carbon. Fig. 67a represents part of the iron-carbon equilibrium diagram.
FIG. 67.—The Carburization and Decarburization of Iron.

Below the Ac$_1$-arrest, at about 720°, ferrite and cementite appear; above that temp. the system contains one or two solid phases. Between A' and A (0 to 0·35 per cent. carbon) the system at, say, 800° contains ferrite and austenite; between A and B (0·35 to 1·05 per cent. carbon), austenite only; whilst between B and B' it contains austenite and cementite. The variation in the proportion of carbon in austenite, at 800°, is shown in Fig. 67b. The proportion is constant below A (about 0·35 per cent. carbon), though the qualities of ferrite and austenite vary with the proportion of total carbon, but the austenite does not hold less than 0·35 per cent. carbon. Between A and B, where austenite alone is present, the proportion of carbon in the austenite is the same as in the alloy. At and above B the austenite is saturated with carbon, so that its composition is constant. A higher proportion of carbon alters only the relative proportions of cementite and saturated austenite.

The reaction $3Fe+2CO \rightleftharpoons Fe_3C+CO_2$ represents a bivariant system in the presence of two solid phases, and tervariant in the presence of one solid phase between A and B, the additional variable being the carbon vap. press. of the austenite. Consequently, the proportion of carbon dioxide in the stable gas ought to vary with the proportion of carbon in the alloy, as shown diagrammatically in Fig. 67c. If more carbon dioxide is present, the carbon press. is lower along AA'; an equilibrium is established between the gas and ferrite and austenite of the lowest

concentration. The same will occur from A to B, between the gas and austenite; the percentage of the carbon of the austenite rises between A and B. Likewise, an equilibrium prevails along BB' between the gas and cementite and saturated austenite. If it were possible for austenite at 800° to have a lower proportion of carbon than 0·35 per cent., the curve AB would continue to rise as indicated by the dotted line. This does not occur, so that the curve AB will be intersected by AA' at A, which gives the carbon content of the alloy whose A_3-arrest is saturated at 800°.

M. L. Becker found that the composition of the gas in equilibrium with graphite varies over a range of temp. from 650° to 1000° in accord with the measurements of A. Johansson and R. von Seth, and others. The gas in equilibrium with iron carbide plus a saturated solid soln. is richer in carbon monoxide than that in equilibrium with graphite at the same temp. The carbon vap. press. of iron carbide, between 650° and 1000°, must in consequence be higher than that of carbon alone. Graphite is therefore stable with respect to iron carbide over this range of temp., and this conclusion is not in agreement with that of A. Matsubara, and A. Johansson and R. von Seth, who inferred that the vap. press. of the carbon of the carbide is lower than that of graphite at temp. exceeding 800°. M. L. Becker observed that the presence of silicon raised the ratio CO : CO_2 for steels of a given carbon content ;
FIG. 68.—The Carbon Pressure as a Function of the Carbon Content of the Solid Phase.
FIG. 69.—The Carbon Pressure as a Function of the Temperature.

manganese and nickel had no perceptible effect on the gaseous equilibrium ; and chromium lowered the carbon vap. press. of a solid soln.

Observations on the constants of the reactions were discussed in connection with the reactions in the blast-furnace ; and since K_1 and K_3 are known, it follows from (1) that the carbon press. of cementite and solid soln. can also be calculated, since these stand in the same relation to the press. of elementary carbon as $K_1 : K_3$. Continuing, A. Johansson and R. von Seth observed that the isotherms of the carbon press. as functions of the carbon content of the solid phase are shown in Fig. 68, where [C_3] is a constant for each temp., so that the curves represent [C_2] as a function of the carbon content at each temp. respectively. This function is almost rectilinear for solid soln., meaning that the carbon press. of austenite increases proportionally with its carbon content, and thus follows the same law as the osmotic press. of a dil. soln. The carbon press. of cementite does not increase with increasing temp. as rapidly as that of austenite, and it follows that the higher the temp. the lower the carbon content of austenite. An equal carbon press. is not attained until the austenite is saturated with carbon. For instance, the isotherm at 1000°, where the curve of the carbon press. of austenite bends before the point A is reached, and passes into the cementite line at B. The relation between the carbon press. and temp. is shown in Fig. 69. Below the line 1·0, the carbon press. of cementite and

solid soln. is less than that of carbon ; above 1·0 per cent. of carbon, it is greater than that of carbon. An atm. of carbon monoxide and dioxide in equilibrium with elementary carbon is therefore unable to carburize the iron until about 735° (A, Fig. 69) is attained, when austenite with about 0·7 per cent. of carbon is formed. The carbon content of austenite is increased with a rising temp., but no free cementite is formed until about 790° (B, Fig. 69). Below 735°, decarburization always occurs in such an atmosphere. A steel with an excess of cementite is decarburized at 790°. This shows the risk of surface decarburization in the annealing of steel. In the surface decarburization of steel by dry carbon dioxide and monoxide, mixed with 60 per cent. nitrogen, as well as by dry air—at 750°, 800°, 900°, and 1100°—the results, in general, can be represented by Fig. 70, showing the depths of carburization in mm. and the carbon content of the layer in percentages. The stippled area shows the amount of decarburization below a plane surface, and is represented as the degree of decarburization—per cent. mm. When the degree of decarburization is represented as a function of the proportion of carbon dioxide in the gas, the curve rises at first very rapidly, with an increasing content of carbon dioxide, reaching its highest value with 10 per cent. carbon dioxide for the hypoeutectoid steels and with 15 per cent. carbon dioxide for the hypereutectoid steels. It then remains nearly constant for higher percentages of carbon dioxide, although the speed of the reaction ought to have increased. The maximum degree of decarburization may possibly be determined by the speed of diffusion of the carbon ; but it ought to be observed that the formation of oxide-scale on the surface of the specimen sets in at the breaks in the curves. It is therefore also possible that the oxide-scale in some way represses the decarburization, presumably by protecting the underlying surface of the steel from the influence of the gases, thus rendering the diffusion of the gas more difficult. The results are similar at 900° ; the hypoeutectoid steel reaches its maximum decarburization with 15 per cent. carbon dioxide, and with the hypereutectoid not until about 25 per cent. carbon dioxide is attained. The formation of oxide-scale sets in with about the same percentages of carbon dioxide. At 800°, the formation of the oxide-scale has so great an influence on the degree of decarburization that the latter, after having reached its maximum with about 25 per cent. carbon dioxide, decreases considerably with higher proportions. The hypoeutectoid steel here decarburizes more than the hypereutectoid steel, while the contrary is the case at 900° and 1100°. A somewhat stronger decarburization is obtained in air than in gases containing 40 per cent. carbon dioxide. No decarburization occurs at 750°, 710°, and 650°. Practical use has also been made of this circumstance, but the explanation generally suggested— namely, that the formation of oxide-scale should proceed *pari passu* with the decarburization, no surface decarburization thus taking place—seems to be wrong. The oxide layer is much too thin to be able to act in this way. Instead, as at higher temp., it appears simply to form a protective layer against the influence of the gases.

The phenomenon was also studied by E. Zingg and co-workers, H. Schenck, C. R. Austin, P. Oberhoffer and J. Welter, H. C. Greenwood, R. G. Guthrie, J. J. Curran and J. H. G. Williams, E. Leuenberger, J. G. Ayres, A. Bramley and K. F. Allen, A. Seuthe, etc. L. Hackspill and E. Schwarz, and A. M. Portevin and V. Bernard observed that at 1000° the chlorides and carbonates of the alkali and alkaline-earth metals effect the superficial decarburization of cast iron and steel ; and that in 2 to 3 hrs. the carbon is almost completely removed from hypoeutectoidal steels to a depth of about 1 mm. They suggest that the active agent in this reaction is the alkali or alkaline-earth metal liberated from its salt by the iron. Calcium rapidly removes carbon and phosphorus almost completely from cast iron 1 to 2 mm. thick at 1000°, forming calcium carbide and phosphide.

Fig. 70.—Decarburization Curve.

Lithium behaves similarly above 450°, but sodium and potassium above 800° act much more slowly, as the carbides formed are relatively unstable at the ordinary press. Sodium carbide has been made by direct union of the elements under press. at 1100°.

§ 10. The Cementation of Iron and Steel

One of the oldest commercial methods of making steel is by what is now known as the cementation process. The purpose of **cementation** is partially or totally to carburize iron or steel without fusing the metal, and in such a way that the carburized metal shall possess the structure and properties of a true steel. This is done by heating wrought-iron bars packed in boxes made from a fireclay. Each bar is surrounded by broken charcoal, heated to 950° or 1000°, and kept at this temp. until the desired percentage of carbon has been absorbed from the charcoal. The carburizing agent may be solid—*e.g.* wood-charcoal, lampblack, and various organic substances like hoofs, hides, dung, etc.; it may be liquid—*e.g.* fused cyanides or ferrocyanides, urine, or molten cast iron; or it may be gaseous— *e.g.* volatile hydrocarbons or carbon monoxide.

Mixtures and methods have been discussed by R. R. Abbott,[1] A. A. Ackermann, F. André, F. G. Bates, C. Binks, G. F. Hinkens, J. F. J. A. Boullet, P. W. Brennan, H. L. Heathcote, R. A. Millholland, S. A. Teschenko-Tschopiwsky, V. Grönquist,

J. Herbert, G. Takahashi, J. S. Ayling, P. W. Döhmer, J. W. Urquhart, S. Tour, R. A. Brooman, G. B. Cattaneo and A. Faggian, M. F. Coomes and A. W. Hyde, F. Cowden, V. H. E. Gallot, J. Holland, J. B. Jenkins, N. Kimball, M. B. Messimer and E. F. Carter, W. Nelson, S. P. Rockwell, E. C. Moffett, T. Langer, C. Lamargese, J. Lecarme, and G. C. Thomas, R. A. Ragatz and O. L. Kowalke, G. M. Enos, and by numerous others. The Cyanide-Gesellschaft proposed to use cyanamide or one of its compounds with the alkalies or alkaline earths; and E. Engels, carbon silicide. J. C. Olsen and W. S. Weissenbach observed that the relative carburizing action of carbon monoxide, acetylene, and methane is in the order named. *H. Caron's cement* is a mixture of 60 parts of carbon (wood-charcoal) and 40 parts of barium carbonate; *F. Giolitti's cement* is carbon assisted by carbon monoxide. C. Macintosh, and G. Vismara obtained steel by the action of hydrocarbons at a white-heat; but D. Mushet found that the difficulties in keeping the containing vessels air-tight at the high temp. were insuperable.

The time of heating depends on the thickness of the desired coating, the temp. of the furnace, and the nature of the carburizing agent. In certain cases where a metal with a tough interior and a hard working surface is required the piece is made from a mild steel with about 0·14 per cent. of carbon. The piece is then subjected to the cementation process, so that its carbon content is raised to about 0·9 per cent. The piece is then quenched from a red-heat, say 800°, whereby the outer surface is hardened without affecting very much the mild steel core. In the case where all or part of the surface of a steel or iron object is carburized and subsequently hardened, the operation is called **case-hardening.** If a particular part of the surface is not to be carburized, it is protected by some inert material—fire-clay, electrodeposited copper, etc. The technology of case-hardening and cementation is discussed in special books :

H. Brearley, *The Case-Hardening of Steel*, London, 1921; F. W. Harbord, *The Metallurgy of Steel*, **1.** 241, 1916; F. Giolitti, *La cementazione dell'acciajo*, Torino, 1912; *La cémentation de l'acier*, Paris, 1914; *The Cementation of Iron and Steel*, New York, 1915; F. W. Rowe, *Iron Steel Ind.*, **3.** 77, 116, 1930; J. W. Urquhart, *Steel Thermal Treatment*, London, 1922; A. M. Portevin, *Pyrométrie et cémentation*, Paris, 1920; E. Menzel, *Das Härten, Schweissen und Löten von Stahl und Eisen nebst vielen Rezepten zur Herstellung praktischer Helfsmittel*, Berlin, 1921.

J. Beckmann said that he was not able to find any reference to the manufacture of steel by cementation in any of the ancient writings, and that the obscure reference in Pliny's *Historia naturalis* (**34.** 41) does not refer to this process. Towards the end of the eleventh century, P. Theophilus described the hardening of files by carburization; and the old process was described by V. Biringuccio in 1540; by G. Agricola in 1561; by G. J. Löhneyss in 1617; by M. Lister in 1693; and in later years, by J. Buttery, J. R. Bréant, H. Damemme, L. B. G. de Morveau, G. Vismara, and P. C. J. B. Tronson du Coudray.

Attempts to trace the origin of the cementation process of steel manufacture have not been successful. R. Jenkins supposed that the process was invented by W. Ellyott and M. Meysey, as indicated in their patents of 1614 and 1617. The older writers, C. J. B. Karsten, A. L. Landrin, J. Franquoy, etc., state emphatically that the cementation process was invented on the Continent and not in England. D. Brownlie examined the claims of W. Ellyott and M. Meysey and showed that a strong protest against the patent monopoly was made at the time by the iron and steel manufacturers, and that the patented process would not furnish cementation steel. The reference of R. Plot to the manufacture of cementation steel at Bromley, Staffordshire, shows that in 1686 he regarded the process as new and unusual. J. Franquoy stated in 1861 that the two armourers P. du Coudraye and J. van Buhl of Liége made steel out of iron by the cementation process at the beginning of the seventeenth century. After examining the original documents, Baron de Laveleye concluded that there is nothing to show that the cementation process was here employed, although, about this period, the cementation process seems to have been employed in the principality of Liége for making steel from iron. Baron de Laveleye, and D. Brownlie therefore conclude that how or when the cementation process was invented remains unknown.

As indicated above, the phlogiston chemists—T. Bergman, and C. W. Scheele—believed that steel is a compound of iron with variable proportions of plumbago ; and that plumbago is a compound of fixed air and phlogiston. R. A. F. de Réaumur showed that the transformation proceeds from the surface towards the interior of the mass ; and that the foreign substance which penetrates into the iron and increases its weight is contained in the powders used as *cement*. He wrongly inferred that the substances which penetrate the iron during the cementation are sulphur and volatile salts. C. A. van der Monde, C. L. Berthollet and G. Monge, however, inferred that the foreign substance which combines with pure iron to form steel is no other than the element carbon. They showed that, as already observed by R. A. F. de Réaumur, iron is transformed into steel by merely heating it with wood-charcoal alone and protected from contact with air or moisture. The transformation is attended by an increase in weight owing to the gradual absorption of carbon by the iron.

To the early observers it appeared that in cementation solid carbon can readily penetrate the pores of solid iron when dilated by heat. The phenomenon was said to be *une opération inexpliquée, mystérieuse, présentait le carbone comme un corps anormal*, because it seemed to contradict what was thought to be a law of nature—*corpora non agunt nisi soluta*. The process was therefore regarded as obscure and mysterious. A. Laurent suggested the improbable hypothesis—the *carbon vapour hypothesis*—that it is the vapour of carbon itself which penetrates the iron during the cementation. P. G. F. Leplay attempted to explain the carburizing action of wood-charcoal by assuming that the oxygen of the air contained in the cementation boxes reacts with the carbon, forming carbon dioxide and subsequently carbon monoxide. The latter penetrates the iron, depositing half its carbon to form carbon dioxide. This is again reduced to carbon monoxide by the carbon of the cementing agent. The carbon monoxide—in the *carbon monoxide catalyst hypothesis*—thus acts as a carrier of oxygen by a cycle of reactions continued indefinitely. The hypothesis was favoured by A. Laurent, and H. Behrens and A. R.. von Linge ; and a modification of this hypothesis—*vide infra*—is the one now generally accepted. J. L. Gay-Lussac emphasized that there is no need to accept in *une foi aveugle* the ancient principle, because solids, liquids, and gases can act on one another, though the solid state is the least favourable to the exercise of chemical affinity. J. L. Gay-Lussac's hypothesis—the *diffusion of solid carbon hypothesis*—reduces the phenomenon to the assumption that solid carbon can diffuse into solid iron and at the same time carburize the iron.

W. H. Pepys proved that iron can be directly carburized by heating an iron wire in contact with diamond dust ; analogous observations were made by L. Clouet, D. Mushet, G. S. MacKenzie, L. B. G. de Morveau, P. A. Dufrénoy, and F. Margueritte; while W. C. Roberts-Austen repeated the experiment by heating electrically a strip of iron while in contact with small diamonds at a temp. far below the m.p. of iron, and in vacuo, so as to preclude the presence or influence of occluded gas. W. Hempel heated the iron in contact with different forms of carbon in an atmosphere of nitrogen. He said that the lowest temp. at which the diamond carburizes is 1160° ; and that amorphous carbon, between 1385° and 1420°, forms grey cast iron. F. Osmond observed that at 1035° to 1065° iron is carburized by diamonds about the points of contact ; and at 1085° to 1125°, with diamonds in the proportion of 4 per cent., the diamonds dissolve in the iron to form white cast iron ; and with diamonds in the proportion of 8 per cent. fused grey cast iron is formed to which adheres a graphitic patina containing iron. The diamond itself does not cement iron until it has undergone a molecular transformation into graphite. While the carbon diffuses into iron, the iron also diffuses into the transformed diamond.

W. C. Roberts-Austen studied the rate of diffusion of carbon in solid iron. He represented the variation in the concentration of the carbon in successive layers of the carburized zone in a cemented steel containing originally 0.26 per cent. of carbon. Observations on the diffusion of carbon were reported by G. Tammann

and K. Schönert, J. H. Hruska, E. G. Mahin and co-workers, E. Zingg, J. Parry, A. Fry, F. Abel, I. Runge, F. Osmond, and J. E. Stead; and on diffusion in solid soln. in general, by H. Braune and H. Hellweg, J. H. Hruska, and C. H. Desch.

G. J. Snelus regarded the direct union of carbon with iron as analogous with a process of solution rather than of chemical combination. J. O. Arnold thought that the carbon diffused in the form of the two carbides Fe_3C and $Fe_{24}C$; the former begins at about 950° and the latter at 750°. W. C. Roberts-Austen supposed that the carbon diffused in iron as salt does in water until the saturation point is attained. There is nothing very definite to show whether it diffuses as carbon or as carbide.

FIG. 71.—The Depth of Penetration of Iron by Carbon.

A. Colson emphasized the reciprocal nature of the process of diffusion—while carbon diffuses into iron, the iron diffuses into carbon. The phenomenon is manifest at 250°, when the diffusion of iron into carbon is predominant; at higher temp. the reciprocal process prevails and cementation occurs. L. Forquignon also noted the decarburization of cast iron when it is ignited with powdered charcoal and subjected to the same conditions as would carburize steel. A. Gautier, A. F. E. Degen, R. Mannesmann, and I. L. Bell also noted that when cast iron in contact with wrought iron is heated, carbon passes from the former to the latter—maybe by diffusion, maybe by the intervention of gases, say carbon monoxide. G. P. Royston found that no diffusion occurred at 900° in vacuo when two bars of soft steel with 0·15 per cent. of carbon were kept in contact with a bar containing 0·95 per cent. of steel, but if a more highly carburized bar was employed, the proportion of carbon in the bars of mild steel rose from 0·15 to 0·29 per cent., and the proportion in the highly carburized bar fell to 0·42 per cent. This shows that carbon diffuses into iron by simple difference of concentration, without the intervention of gases. J. O. Arnold and A. McWilliam obtained an analogous result.

C. R. Austin observed that the diffusion of carbon proceeds until the concentration and pressure of the diffusing substance attain a constant value, and the constant of diffusion—that is, the amount of carbon which would diffuse across unit area under a concentration gradient of unity in unit time (say one day), if the rate were constant during that time—was estimated to be 0·005 at 650°, and 0·05 at 850°. A round steel bar containing 1·27 per cent. of carbon was decarburized by moist hydrogen at 680° for 100 hrs. so as to furnish a layer of ferrite and an unchanged core. Pieces of the bar were heated in vacuo. The diffusion of carbon was very slow below the Ac₃-arrest; at 920° the core was freed from cementite and carbon had passed halfway to the surface; at 1000° only a very narrow layer was free from carbon; and at 1100°, in 30 mins., the carbon had passed halfway to the surface, while some cementite still remained in the core. I. Runge determined the rate of diffusion of carbon into iron by measuring the change in the resistance of iron wire in a current of gaseous hydrocarbon at a high temp. Illuminating gas diluted with hydrogen had little or no action; toluene diluted with nitrogen reacted slowly, more quickly when diluted with hydrogen; whilst a rapid action was shown by mixtures of benzene with nitrogen, high petroleum (b.p. 90°–100°) with hydrogen, and hexane with nitrogen or hydrogen. The time-resistance curves were similar to those obtained on the assumption that the diffusion of carbon follows the diffusion law. At 900°, the diffusion coeff. of carbon in iron is about 2×10^{-7} cm. per sec. With an active gas, at 930°, 0·6 mgrm. of carbon passes through 1 sq. cm. of surface in the first three minutes. The resistance change due to 1 per cent. of carbon is 5·7 per cent. at 920°, 7 per cent. at 830°, and 40 per cent. at 18° of the resistance at the corresponding temp. The velocity of cementation falls off rapidly with temperature and is inappreciable at 700°. When cementation takes place above 900°, γ-mixed crystals are formed, and
the product is found to consist of cementite and pearlite. At 800° the β-iron takes up carbon to form an equilibrium mixture of γ-mixed crystals containing about 0·3 per cent. of carbon and β-iron. Whether diffusion takes place in the gaseous form or as carbon cannot be affirmed, but the marked influence of hydrogen on the rate of diffusion points to the former. The subject was studied by N. Agéeff and M. Zamotorin.

G. Tammann and K. Schönert gave for the diffusion coeff. of carbon in iron with 0·07 per cent. of carbon 3×10^{-7} at 925°, and $19·3 \times 10^{-7}$ at 1000°; and for iron with 0·26 per cent. carbon, $11·2 \times 10^{-7}$ at 1000°. I. Runge gave for electrolytic iron $1·15 \times 10^{-7}$ at 925°. A. Bramley and A. J. Jinkings also found for iron with 0·02 per cent. carbon, $1·7 \times 10^{-8}$ at 850°; $3·8 \times 10^{-8}$ at 900°; $9·0 \times 10^{-8}$ at 950°; and 20×10^{-8} at 1000°. Different results were obtained by varying the rate of flow of the carburizing gases, and with steels containing different proportions of carbon. A. Bramley and co-workers found that the diffusion of carbon follows the law :

$$C = \frac{H}{2\sqrt{\pi K t}} e^{-\frac{x^2}{4Kt}}$$

where C denotes the concentration of carbon above that initially present in the steel at a depth x cm. below the surface ; t denotes the time of diffusion in seconds ; H, a numerical constant ; and k, the diffusivity constant. For armco iron at 1000°, $H=0·312$ to $0·320$, and $k=13·0 \times 10^{-8}$ to $15·0 \times 10^{-8}$; whilst for Swedish iron at 1000°, $H=0·310$ to $0·320$, and $k=18 \times 10^{-8}$. T. Ishiwara said that the rate of diffusion, V, of carbon in iron increases rapidly with rise of temp., $\theta-\theta_1$, so that between 950° and 1300°, $V=e^{a(\theta \cdot \theta_1)}$ cm. per second, where a is a constant—in one case $a=0·00986$, and $\theta_1=2220°$; and

	1300°	1200°	1100°	1000°	950°
$V \times 10^6$ . .	111·00	43·19	16·20	5·981	3·616

The work of F. Osmond, also, has demonstrated the great molecular mobility of solid iron at a temp. at least 600° below its m.p.—*vide infra*, the decarburization of cast iron.

F. Margueritte, C. E. Jullien, R. Mannesmann, A. Ledebur, and R. S. Marsden favoured the opinion that cementation can take place by simple contact ; J. Percy, and L. Guillet held the contrary opinion. R. Mannesmann said that the maximum concentration of carbon, 4·76 per cent., which iron can take up by direct contact in the process of cementation is the same as that obtained by the diffusion process. It is therefore necessary to admit the molecular migration of carbon by diffusion into the mass of solid iron. These two processes must therefore play a part in the practice of cementation. Iron at the temp. of cementation is said to behave as a very viscous liquid in which the mobility of the molecules is shown by the tendency to form a coarsely crystalline structure when the iron is heated for a long time at a high enough temp. Carbon has a tendency to migrate from more highly carburized zones to less carburized zones. This agrees with the observations of J. B. J. D. Boussingault on the molecular migration of other elements—sulphur, phosphorus, silicon, and arsenic—in iron and steel. The movements of carbon in steel were discussed by W. E. Day, and W. Metcalf and J. W. Langley, and F. W. Adams. T. H. Byron showed that the carbide is formed by the action of blast-furnace gases ; and H. C. H. Carpenter and C. C. Smith, that a carbide, probably Fe_3C, is formed by the action of carbon monoxide on iron at about 650°. The formation of this carbide is hindered by the presence of carbon dioxide, and favoured by the presence of hydrogen. M. L. Becker studied the carburization of iron by the gaseous carbon oxides.

J. Garnier in a memoir, *Action de l'électricité sur la carburation du fer par cémentation*, reported that he had placed a bar of steel containing only 0·1 per cent. of carbon, and a rod of gas carbon, end to end in a refractory tube and the two were well insulated. The tube was then heated at 900° to 1000°, and a current of

55 ampères and 7 volts was passed from the carbon to the steel. After three hours it was found that that part of the iron opposed to the carbon cut glass easily, and a section showed that cementation had taken place to a depth of about 10 mm., whilst the carbon was corroded at the surface of contact. Two bars of steel were then packed side by side in wood-charcoal with a space of 10 mm. between them, and were heated at 900° to 1000° for three hours, a current of 55 ampères and 2·5 volts being passed from one to the other. It was found that the bar which served as the anode was practically unaffected, whilst in that which played the part of the cathode cementation had occurred to a considerable depth. It would seem, therefore, that at about 1000° the cementation of iron takes place with very great rapidity under the influence of a comparatively weak electric current. Attempts to accelerate cementation by means of an electric current, applied independently of its heating effect, were made by R. K. Boyle, G. Mars, and A. Hillairet.

G. P. Royston stated that below the Ar_1-arrest carbon has no tendency to diffuse into iron. The limit of saturation at 700° corresponds with 6·9 per cent. of carbon, and, according to E. H. Saniter, the limit at 900° is 2·95 per cent. F. Osmond pointed out that the limit of carburization of solid iron at a given temp. represents the solubility of cementite at that temp.; and at about 670°, the recalescence temp., this limit is 0·9 per cent., and this increases with a rise of temp. The limits of solubility do not represent definite compounds $Fe_{14}C$, $Fe_{24}C$, etc., otherwise there would be an indefinitely large number of such compounds. One of J. O. Arnold's micrographs shows an abrupt variation in the concentration of the strata corresponding with the surface of contact of the hypereutectoidal and eutectoidal steel—vide infra, Fig. 70. He supposed that the diffusion of carbon takes place in two ways: the first begins at about 750°, the Ar_2-arrest, between iron and the alleged subcarbide, $Fe_{24}C$, whilst the second takes place above 950° between the normal carbide, Fe_3C, and the subcarbide, $Fe_{24}C$. This shows how, at 800°, it is not possible to increase cementation beyond 0·9 per cent. carbon, the proportion in $Fe_{24}C$, and why the cementation must be conducted at higher temp. if a more highly carburized steel is required. J. O. Arnold and A. McWilliam reported that when pure iron at 950° to 1050° is in contact with iron containing 1·5 per cent. of copper, aluminium, silicon, arsenic, chromium, and tungsten, no diffusion of these elements occurred in 10 hrs., but with carbon the percentage diffusion was 0·50; with sulphur, 0·10; with phosphorus, 0·095; and with nickel, 0·11. For the effect of various elements on the velocity of cementation, vide infra. S. C. Spalding, and J. Sorenson compared the rate of penetration in various kinds of carbon and alloy steels. G. Takahashi studied the relation between the quantity and depth of carburization.

F. W. Harbord, A. S. Stansfield, E. H. Saniter, and A. Ledebur doubt the hypothesis of diffusion involving the dubious subcarbide, particularly when the phenomena can be explained simply by the passage of carbon from molecules richer in it to those containing a smaller amount, by a process entirely analogous to that of diffusion in saline soln. G. Takahashi concluded that the carburization of steel is not due to the diffusion of carbon monoxide, but to the direct diffusion of nascent carbon atoms produced by the decomposition of that gas. H. Louis suggested that the diffusion of nickel into solid iron may be due to the formation of a nickel carbonyl.

In conformity with a suggestion of H. W. Stein, H. Caron tried to establish the hypothesis that the process of industrial cementation is always due to the action of volatile cyanides—volatile cyanides hypothesis—the cyanides acting as carriers of carbon to the iron. The work of H. Caron was discussed by P. Nicolardot. H. Caron obtained no cementation when iron is heated with carbon in the presence of hydrogen, carbon dioxide, nitrogen, and air. In this H. Caron went wrong. He attributed the carburization he obtained with ammonia gas to the preliminary formation of ammonium cyanide and he found that ammonium cyanide alone is a powerful cementing agent. He also found that with carbon in the presence of alkalies and alkaline earths which can form cyanides in air cementation occurs. The favourable effects obtained with a mixture of barium carbonate and carbon were attributed to

the preliminary formation of barium cyanide. Wood-charcoal was supposed to act in virtue of its forming cyanides by the action of carbon and the nitrogen from the air on the ashes of the carbon. C. Binks also concluded that in order to carburize iron it is necessary for nitrogen (*e.g.* ammonia) and carbon (*e.g.* ethylene) to act simultaneously; no cementation occurred with carbon, carbon monoxide, ammonia, or ethylene alone. H. Caron emphasized that the more easily the carburizing agent is decomposed the greater is the concentration of the carbon in the cemented iron; thus ammonium cyanide is the most effective cementing agent among the cyanides, and is the one most easily decomposed. L. Cailletet did not find cyanogen or cyanides in his analysis of the gases present in the cementation boxes.

E. Frémy considered that nitrogen is a necessary constituent of steel—*nitrogen hypothesis*—since the gas has been always found to be occluded in steel; he went so far as to say that iron is converted into steel (*acière*) by absorbing nitrogen (*azotant*) in the presence of carbon, and that steel is changed to iron (*désacière*) by removing its nitrogen (*désazotant*) by hydrogen; the function of nitrogen is not only that of forming cyanides, which carry the carbon in a state of combination into the pores of the iron, where the iron absorbs the carbon in the nascent state, but also that of serving as a vehicle for the penetration of the carbon into the iron, and taking part directly in the formation of steel, since it forms a kind of cyanogen compound which is an essential constituent of steel. He regarded steel not as a simple carbide but as a nitrogenized iron carbide. E. Frémy's hypothesis excited some interest, but H. Caron's experiments on the cementation of iron by hydrocarbons showed that the nitrogen hypothesis is untenable. H. Caron, however, not only disproved E. Frémy's hypothesis, but he also considerably weakened his own. For instance, in cementations obtained with purified methane and other hydrocarbons cyanides are absent. He therefore said that hydrocarbons, on account of their too easy decomposability, carburize the iron too much, transforming it into cast iron instead of steel; and added that the alkali cyanides are the only compounds capable of producing a true cementation under industrial conditions. F. Margueritte in a controversy with H. Caron showed that cementation can occur (i) by simple contact without the intervention of nitrogen; and (ii) by the action of carbon monoxide. H. Caron said that charcoal, under industrial conditions, becomes exhausted with use, and is then incapable of carburizing iron. This is not likely to be the case if, as F. Margueritte supposed, carbon and carbon monoxide are the most active agents in industrial cementation. H. Caron attributed the decreased efficiency of used charcoal to the loss by volatilization of alkalies, for the charcoal can be rendered inactive by washing it with acid to remove at least some of the alkali; the activity of the charcoal can be restored by the addition of alkali; and the varieties of charcoal richest in alkali are the most efficacious. F. Margueritte attributed the exhaustion to its acquiring a more compact atomic structure by the prolonged heating, a view favoured by R. Mannesmann. H. Caron admitted that carbon monoxide can produce a slight cementation, but he said that it is not produced at a red-heat, but rather during the cooling, when the decomposition of carbon monoxide is possible. C. E. Jullien said that carbon alone can carburize iron, but carbon monoxide does not do so under industrial conditions. J. Percy, on the other hand, found that purified sugar charcoal, freed from occluded gases, cannot carburize iron, except at a temp. high enough to melt the product. There is thus one school which assumes that a gas is necessary for the continued diffusion of carbon—*gaseous diffusion theory*—and another school which believes that the carbon penetrates the metal without the intervention of a gas—*solid diffusion theory*.

R. Mannesmann showed that the *concentration* of the carbon in the cemented crust and the *velocity* of penetration of the carbon vary with the progress of the cementation. He showed that the variation in the gradual increase in the velocity of penetration agrees rather with the hypothesis that the action is mainly due to the molecular migration of carbon, and is not due solely to the action of gases, for in this case the cementation should proceed with increasing slowness as the deeper layers

of the mass are reached. When the cementation is not effected by free carbon, but by a compound of carbon, the degree of carburization is proportional to the difference between the affinity of carbon for iron and the affinity of carbon for the substances with which it is combined. Hence, at a given temp., free carbon can give a higher carburization than when the contact is sufficiently prolonged. The cyanides are specially suited for obtaining thin, superficial cemented layers, and to cases where it is desired to work at low temp., where the molecular migration of carbon is slow ; solid carbon is best for producing deep, highly carburized cementations. He found wood-charcoal does its work faster than graphite. The velocity of cementation was found to be smaller the greater is the initial concentration of carbon in the steel to be cemented ; but with an equal velocity of cementation the work of cementation required for saturation is less the greater is the proportion of carbon in the sample to be treated. Owing to the lowering softening temp. with increasing proportions of carbon in steel, and since an increased mobility facilitates the migration of the carbon, the cementation is effected more rapidly the harder the steel, and steel is cemented more rapidly than iron. In general, it is considered that the gases formed in the cementation boxes containing carbon are so dil. as to render negligible their carburizing action, even if some of them—*e.g.* carbon monoxide— have a stronger carburizing action when sufficiently concentrated. The carburization produced by the penetration of gases into the iron plays but a small part in the process of cementation, and is limited to a superficial zone of small depth. The main work is done by the molecular migration of carbon into the deeper layers of iron—*vide infra.*

G. Charpy showed that by heating filings of soft iron in fused potassium cyanide at about 650° for about 86 hrs. it is possible to transform the metal completely into iron carbide containing 6·67 per cent. of carbon. At higher temp. the iron carbide decomposes, giving graphite. Thus steel heated in a current of coal gas for 64 hrs. at 1000° gives a product with 8·32 per cent. of carbon, of which 7·66 per cent. is graphite ; and with carbon monoxide for 36 hrs. at 1000° the product has 9·27 per cent. of carbon, of which 8·27 per cent. is graphite. Hence, added G. Charpy, the cementation is not limited by the solubility of carbon in iron. It is possible to obtain either the transformation of iron into the carbide or the indefinite transformation of carbon into graphite. G. Charpy heated iron in a slow current of purified carbon monoxide, and observed that cementation occurs at 560° ; in 8 hrs. a deposit of carbon was formed at 560°, 600°, and 715° ; while in 2 to 3 hrs.' heating the following relative weights of carbon were fixed by the metal :

	825°	935°	1025°	1085°	1125°	1175°	1185°	1190°
Carbon	0·60	0·60	0·58	0·58	0·47	0·51	0·47	0·33

Hence, above 750° no deposit of carbon is formed and the cemented metal remains polished and bright ; the velocity of cementation (not penetration) does not increase appreciably above 900°. The cementation is limited if instead of working in a current of gas the steel is heated in a limited quantity of carbon monoxide, for in that case cementation ceases when the proportion of carbon dioxide formed reaches a certain limiting value : $2CO \rightleftharpoons C + CO_2$. He inferred that the cementation can be conducted in such a way that the quantity of carbon absorbed is automatically regulated by using as cementing substance a continuous current of a gaseous mixture containing definite proportions of carbon monoxide and dioxide, cyanogen and nitrogen, or hydrocarbons and hydrogen. F. Giolitti could not truly cement low-carbon steels below 780°. It is here necessary to distinguish different meanings of the term carburization. With cementation proper there is a cemented zone which not only contains an increased proportion of carbon (carburization), but possesses the characteristic structure of steel having a high carbon content. This structure results from the segregation in iron during the cooling of a solid soln. of carbon to a state of cementite, and this soln. cannot be formed below 780°. This temp. therefore represents the lower limit at which true cementation can occur.

L. Guillet stated that cements composed of carbon alone—*e.g.* sugar carbon, wood-charcoal, or graphite—cannot act by a simple soln. of the carbon by the iron in contact with it, for pure carbon does not cement iron in vacuo—*vide supra.* The subject was discussed by O. Bauer. L. Guillet, and R. Bruch observed that the velocity of penetration varies greatly with the temp. In some cases a difference of 100° can double the velocity of penetration. F. Giolitti measured the depth of the cemented zones at different temp. for different periods of time when soft steel is cemented by a mixture of ground wood-charcoal, potassium ferrocyanide, and barium carbonate. The results are summarized in Fig. 72. Other curves show how the temp. of cementation and the time occupied by the operation greatly influence the form of the curves representing the distribution of carbon in the cemented zones. L. Guillet showed that a cement containing carbon can act by means of carbon monoxide formed by the action of air in the cementation boxes; but carbon monoxide acts slowly in virtue of the reaction $2CO \rightleftharpoons C + CO_2$; carbon dioxide has a decomposing action. R. Bruch said that the cementing action of carbon dioxide is nil. L. Guillet classified cements into (i) those whose activity is due to carbon monoxide ; (ii) those whose activity is due to the presence of a cyanide ; and (iii) those whose activity is due to hydrocarbons. The cyanogen group when decomposed liberates carbon ; and the hydrocarbons act by dissociation. As a rule, at 1000° the velocity of penetration of carbon is about the same for all cements, but at the beginning the velocity varies widely from cement to cement. L. Guillet believed that the active agent in every industrial cementation is a cyanide or a carbide, and not carbon alone ; on the contrary, A. Ledebur maintained that the active agent is carbon—*vide supra.* L. Guillet concluded that the velocity of penetration of carbon is independent of the initial proportion of carbon in hypo-eutectic steels; it varies with different cements, but reaches the same limit with different cements after acting for 8 hrs. at 1000°. Both H. Caron, and L. Guillet attribute the increased efficiency of wood-charcoal produced by the addition of about 5 per cent. of potassium carbonate to the formation of potassium cyanide in the cementation boxes. In agreement with L. Cailletet, G. Charpy observed no evidence that cyanides are formed during cementation with wood-charcoal, with a mixture of wood-charcoal and barium carbonate, and with animal-charcoal ; only at about 1050° are cyanides formed with the mixture of charcoal and barium carbonate, but cementation occurs between 900° and 1000°. Cyanides are not necessary for cementation ; the observations of H. Caron on the influence of alkalies on cementation by wood-charcoal are explained as readily by the intervention of carbon monoxide as of cyanides. I. Musatti and M. Croce said that the presence of nitrogen in steel or of nitrogen compounds in the cementation gases accelerates carburization by carbon monoxide. According to W. P. Fishel and J. F. Wooddell, the reaction $3Fe + 2CO \rightleftharpoons Fe_3C + CO_2$ sets in between 800° and 1100°, and the depth of penetration increases with temp., whilst the maximum carbon in the outer " case " decreases even though the total carbon increases ; both carbon monoxide and dioxide penetrate iron very slowly at 950° and 1100°, and this at a rate which does not explain the depth of the case produced by carbon monoxide.

By cementing a fine wire of soft steel at 1100° L. Guillet obtained a concentration of 1·9 per cent. of carbon. The structure was uniform and was characterized by the network of cementite usually found in highly carburized steel. A repetition of the cementation resulted in the agglomeration of the cementite network and a re-absorption of carbon. With steel containing over 7 per cent. of nickel it is possible to obtain by cementation a zone with over 0·8 per cent. of carbon and with the characteristic structure of tempered carbon steel, while the external, untempered

FIG. 72.—The Distribution of Carbon in Iron during Cementation.

layer has the martensite structure and hardness of tempered steel. Steels with over 30 per cent. of nickel have the γ-structure, and are cemented at lower temp. than carbon steels. Indeed, a γ-iron steel can be cemented by fused potassium cyanide at 450°. The diffusion of carbon into γ-iron occurs even at ordinary temp. Thus, such a steel cemented at 1000° contained at the surface 1·22 to 1·35 per cent. of carbon, and after 6 months, 0·85 to 0·92 per cent. This showed that the carbon in the periphery continued dissolving in the mass. L. Guillet measured the influence of various elements on the velocity of penetration of carbon, under identical conditions, into steels with 1·5 per cent. of carbon. The carbon showed a velocity of penetration of 0·9 mm. in a given time. With 2 and 5 per cent. nickel the velocity of penetration was respectively 0·7 and 0·5 mm. ; with 0·5 to 1·0 per cent. manganese, 1·1 and 1·2 mm. ; with 1·0 and 2·0 per cent. chromium, 1·0 and 1·1 mm. ; with 0·5, 1·0, and 2·0 per cent. tungsten, 0·9, 0·9, and 2·0 mm. ; with 1·0 and 2·0 per cent. molybdenum, 0·9 and 1·1 mm. ; with 1·0 and 2·0 per cent. titanium, 0·8 and 0·7 mm. ; with 0·5, 1·0, 2·0, and 5·0 per cent. silicon, 0·6, 0·5, 0·4, and 0·0 mm. ; and with 1·0 and 3·0 per cent. aluminium, 0·4 and 0·2 mm. Hence, the substances which retard cementation are those which dissolve in the iron—e.g. silicon, titanium, aluminium, and nickel—while those which accelerate cementation form complex carbides—e.g. chromium, molybdenum, tungsten, and manganese. There was a discussion between L. Guillet, and A. Ledebur on some of these results ; and H. le Chatelier added that it can be regarded as certain that in cementation many gaseous substances permit the rapid transport of carbon to the iron without direct contact of these two substances, and that the diffusion of carbon in contact with iron is also possible. The disappearance of temper-carbon on heating, for instance, is a proof of it, and the only point open to a difference of opinion is whether carbon penetrates directly into iron in the industrial process of cementation.

F. Margueritte observed that most of the common elements exert some influence on carburization, but usually the effect is small. A. Sauveur, and W. J. Merten inferred from L. Guillet's work that elements which form double carbides usually accelerate carbon absorption, whilst those elements which remain in solid soln. with ferrite have the opposite effect. G. Tammann observed that molybdenum, tungsten, nickel, manganese, and cobalt favoured the penetration of carbon up to a certain maximum, and the effect then diminished. Antimony, and vanadium retarded penetration ; whilst aluminium made no appreciable difference. S. C. Spalding found that high percentages of phosphorus and sulphur retarded carbon penetration, but chromium had the opposite effect. B. F. Shepherd also found that chromium-vanadium steels carburize more readily than carbon steels.

J. Lecarme showed that the brittleness of cemented steel is not due to the heating which accompanies cementation ; and that the cementation which occurs at the surface is accompanied by a chemical transformation of the middle of the mass which appears homogeneous throughout. H. Braune, J. Kirner, and A. Petrén and J. Grabe studied the effect of nitrogen on the mechanical properties of cemented steel—vide infra, action of nitrogen on steel. R. Bruch concluded that cementation is a process of diffusion or solution of the carbon which results in a continuous and uniform increase in the carbon content in passing from the nucleus to the periphery. J. O. Arnold found the process discontinuous—vide supra; and R. Bruch's own diagram, Fig. 73 ($\times$10 and then reduced to one-fourth), shows that with a steel cemented by acetylene, at 1050° for 7 hrs., there is an abrupt transition from the external hypereutectoidal zone, rich in cementite, to an intermediate eutectoidal zone of pearlite and a hypoeutectoidal nucleus. F. Giolitti observed cases in which the outer or hypereutectoidal layer is characterized by cementite and pearlite, and has 1·27 to 1·33 per cent. of carbon ; the second or eutectoidal layer contains pearlite alone, and has about 0·9 per cent. of carbon ; and the third or hypoeutectoidal layer is characterized by the presence of ferrite and pearlite. J. Kirner reported that with nitrogenous cements a special constituent is present in proportions which increase with increasing amount of nitrogen. He called it flavite, and said

that it behaves like a solid soln. in steels etched with picric acid, and it then has a yellowish-brown colour and stands out in clear contrast to the other constituents. It disappears when the steels are hardened. B. Strauss showed that flavite can be distinguished by heat tinting. A. Fry inferred that the composition of the eutectoid is 1·5 per cent. nitrogen, and the eutectoidal temp., 580°. He called the eutectoid *braunite*. A. Bramley and F. W. Haywood found that the iron-iron nitride eutectoid has 2 per cent. of nitrogen, and that the eutectoid temp. is 608°. All the structures characteristic of the iron-iron carbide system can be obtained with the iron-iron nitride system, but they are finer in texture. As emphasized by H. Fay, and G. R. Brophy and S. B. Leiter, case-hardening is partly a nitrogenizing and partly a carburizing process. G. F. Hinkens, and S. Satoh studied the cementation of steel with nitrogen or nitrogenous materials—*vide infra*, the action of nitrogen on iron.

Fig. 73.—Three Zones in a Section of Cemented Steel Wire (R. Bruch).

The structural changes which occur in steel during cementation, etc., were discussed by H. Brearley, J. Sorenson, C. H. Herty and co-workers, and C. W. Bildt; and observations on the cementation process, by M. Partiot, H. Braune, E. F. Lake, J. F. Springer, O. M. Becker, E. F. Davis, S. A. Grayson, L. Grenet, H. A. Vanvught, E. R. Markham, H. de Nolly and L. Veyret, A. Sauveur and G. A. Reinhardt, G. S. McFarland, H. M. Crawford, L. Aitchison, T. G. Selleck, R. M. P. Hamilton, T. Murakami and H. Sekiguchi, C. Kluytmans, H. Schagrin, G. S. Scott, C. J. G. Malmberg, W. T. Griffiths, J. Cournot, A. Jaeschke, F. W. Rowe, E. G. Mahin and R. C. Spencer, W. E. Day, P. Henry, D. Uno, W. J. Merten, H. Müller, H. Weiss, B. F. Shepherd, F. Hodson, F. Kurek, F. Robin, H. L. Heathcote, T. Baker, H. Neuhauss, H. Rodman, J. D. Gat, H. Swain, C. O. Bannister and W. J. Lambert, S. A. Grayson, J. Kirner, S. Epstein and H. S. Rawdon, A. C. Sladky and A. F. Schultz, A. M. Portevin. J. C. Olsen and W. S. Wiessenbach, R. G. Guthrie, A. J. Lindberg, D. A. Holt, I. Musatti and L. Dainelli, H. B. Northrup, F. Hebler, F. Rapatz, R. G. Roshong, M. T. Lothrop, and J. H. Nead and J. N. Bourg.

F. Giolitti's observations on the percentage of carbon in successive layers 0·5 mm. thick when steel at 1000° is cemented in a current of ethylene, methane, and carbon monoxide are summarized in Fig. 74. With carbon monoxide the conc. of the carbon does not attain the eutectoidal value 0·9 per cent., and it decreases uniformly and slowly from the surface inwards. Here the conc. of the carbon in the deeper layers varies so little from that in the external layers that it is doubtful if the carbon has simply diffused into the deeper layers; the cementation has been effected by the penetration of the gas into the steel in co-operation with diffusion. With methane and ethylene the external layer is highly carburized, for it attains a value exceeding 0·9 per cent., and as in the case of carbon alone,

Fig. 74.—The Concentration of Carbon in the Successive Zones Cemented respectively by Ethylene, Methane, and Carbon Monoxide.

the distribution of the carbon is characteristic of diffusion by difference of concentration. In general, other things being equal, the conc. of the carbon in the cemented zone is smaller the higher is the temp., for the reaction is exothermic; the conc. of carbon in the cemented zone is smaller the lower is the press. of the gas, because the reaction $2CO \rightleftharpoons CO_2 + C$ is attended by a decrease in volume; and the conc. of the carbon in the cemented zone increases with an increase in the quantity of carbon monoxide which comes in contact with unit surface of steel. The reaction occurs under such conditions that no carbon is deposited, so that the free carbon formed in the reaction $2CO \rightleftharpoons CO_2 + C$ dissolves entirely in the γ-iron. This means that the speed at which carbon is formed is less than the speed at which carbon dissolves in the γ-iron. The carbon dissolves in γ-iron until it has attained a state of equilibrium. The velocity of penetration of carbon by soln. in the γ-iron and the penetration of carbon monoxide into the metallic mass are favoured by increasing the quantity of carbon monoxide which comes in contact with the surface in a given time. F. Eisenstecken studied the cementation of iron by methane.

Hard, homogeneous, quenched steels have a characteristic fracture; but soft steels, carburized by cementation in a more or less deep surface layer, after being subjected to a hardening treatment, present a totally different fracture. The steel breaks along a surface almost parallel to the external surface of the cemented steel, and instead of lenticular masses detaching themselves as in homogeneous steels, the whole surface yields layers more or less thick according to the depth of the cementation. The phenomenon is called *expoliation*. The surface along which the steel expoliates corresponds with zones possessing a different structure or grain. The expoliation was shown by F. Giolitti to be due to sudden variations in the concentration of the carbon. To avoid as much as possible the formation of these layers the cementation should be carried out in the presence of carbon monoxide. The use of cements which furnish carbon monoxide also hinders the formation of hypereutectoidal zones with their dangerous brittleness. These facts also show how the different effects are produced by the so-called gradual or mild cements and by the violent cements.

G. Charpy found that cementation is rather more intense when wood-charcoal is used as a cement in an atmosphere of carbon monoxide than when it is employed in the presence of its own occluded air. F. Giolitti and L. Astorri concluded that the reports by L. Guillet and others that solid carbon does not cement iron are due to lack of sufficiently intimate contact between iron and carbon, for γ-iron dissolves and is cemented by solid carbon. An increase in the pressure of the carbon on the iron, by favouring closer contact, gives an increased cementation. F. Weyl, L. Guillet and C. Griffiths, and F. Giolitti and L. Astorri showed that the direct action of carbon on iron is very small; G. Charpy and S. Bonnerot found that the action is nil. In either case, contrary to the opinions of R. Mannesmann, W. C. Roberts-Austen, and A. Ledebur, the direct action of carbon in industrial cementation must be negligibly small. The preponderating effect is produced by the simultaneous action of carbon and gaseous cementing agents. With wood-charcoal without carbon monoxide, at 100° for 4 hrs., the hypereutectoidal layer was 0·7 mm. thick, the eutectoidal layer was 0·6 mm. thick, and the hypoeutectoidal layer, 0·2 mm. thick, whereas when assisted by carbon monoxide no hypereutectoidal layer was observed, while the eutectoidal and hypoeutectoidal layers were respectively 1·0 and 0·7 mm. thick. Working with six litres of carbon monoxide mixed with the following proportions of liquid benzene, at 1000° for 4 hrs., the thicknesses of the different layers were found to be respectively:

Benzene	.	.	.	1	1·5	2	15	38 c.c.
	Hypereutectoid			0	0·2	0·2	0·7	0·7
Depth	Eutectoid	.		0·7	0·6	0·6	0·4	0·4
	Hypoeutectoid			0·5	0·2	0·2	0·4	0·4

No deposit of carbon was observed in the first experiment, but in the other cases the deposition of carbon became greater as the proportion of benzene increased. It is therefore possible to regulate the concentration of carbon in the external layer from the minimum obtained with carbon monoxide alone to the maximum obtained with hydrocarbon vapour alone. The results show that it is possible to graduate the concentration of carbon in the cemented zones. With carbon in an atm. of nitrogen the results resemble those obtained with carbon in contact with carbon monoxide. J. Kirner showed that with some nitrogenous cements considerable proportions of nitrogen diffuse into the steel, and that nitrogen exercises a marked influence on the cementation. Experiments on the equalizing action of carbon monoxide in the cementation of iron in contact with carbon were made by F. Giolitti and G. Tavanti. The results also agree with the observations of A. M. Portevin and H. Berjot. F. Giolitti also showed that by carburizing the metal in the usual way so as to produce a high concentration of carbon near the surface, and subsequently treating the metal with carbon monoxide alone, the carbon will be distributed more uniformly and the dangerous effects of a hypereutectoidal zone minimized.

F. Giolitti and F. Carnevali found that by increasing the press. of the gaseous medium—carbon monoxide, ethylene, and methane—the velocity of cementation, and the concentration of the carbon in the cemented zones are increased. They also devised a process of cementation by compressed carbon monoxide and free carbon. A superficial oxidation of the case-hardened steel was sometimes observed. G. Charpy studied the action of carbon monoxide at 1000° on chromium, manganese, and various chromium steels and chromium-nickel steels, and concluded that with the various steels in the form of filings the chromium decomposes the carbon monoxide, and there is a simultaneous oxidation of the chromium and a carburiza-into of the iron; the two elements behave as if they were isolated. If, instead of working with filings, pieces of tolerable dimensions are employed, the same phenomena do not recur; the oxidation of the chromium is restricted to the surface layer, beneath which cementation proceeds regularly by diffusion. At 1000° carbon monoxide carburizes iron, tungsten, and possibly also nickel, but it oxidizes chromium and manganese. F. Giolitti and F. Carnevali, however, have shown that the phenomena are more readily explained in the light of R. Schenck's diagram, Fig. 31, discussed in connection with the reduction of iron oxides (q.v.). In the case of cementation with carbon monoxide and dioxide in the presence of wood-charcoal, it follows that at press. above those corresponding with O—the point of intersection of the curves 4 and 5—the simultaneous formation of ferrosic oxide and a solid soln. occurs in the presence of wood-charcoal, where the solid soln. has a concentration of carbon in equilibrium with $2CO \rightleftharpoons CO_2 + C$. At press. ranging between those corresponding with O and Q—the point of intersection of curves 3 and 5—there is a simultaneous formation of ferrous oxide and of the solid soln., also in the presence of wood charcoal. At press. lower than those corresponding with Q the solid soln. is formed alone, also in the presence of wood-charcoal. Only at press. lower than those corresponding with Q can the cementation take place unaccompanied by the oxidation of the metal. Hence, if the press. of the gas is large enough, phenomena analogous to those observed by G. Charpy with chromium steels will also occur with pure iron or with carbon steels, without assuming the selective action implied in G. Charpy's words. G. Takahashi, S. Matsubara, and F. Giolitti discussed the chemical equilibria between the iron, carbon, and oxygen during cementation—vide supra, reactions in the blast-furnace.

The general results of the work of F. Giolitti and co-workers show that (i) the direct action of carbon is exceedingly slight, and it is negligibly small under industrial conditions. (ii) The cyanides, ferrocyanides, etc., exercise on iron a specific carburizing action, but the activity of cements containing free carbon and alkali or alkaline earth carbonate is not due to the formation of volatile cyanides by the action of atm. nitrogen, but to the formation of carbon monoxide by the action

of carbon on carbon dioxide produced by the dissociation of the carbonates. (iii) The carburizing action of nitrogen in the presence of carbon is negligibly small under industrial conditions. (iv) Hydrocarbons exert a direct carburization of iron, but the carburizing action of the finely-divided carbon deposited by decomposing hydrocarbons on the surface of iron has not been established. (v) Carbon monoxide carburizes iron directly at the temp. of the cementation. (vi) The specific action of carbon monoxide is intensified when the gas acts on iron in the presence of free carbon. This specific action—modified by other carburizing substances present, e.g. hydrocarbons and cyanides—preponderates enormously above all other in all cements in which carbon monoxide is present or can be formed. F. Giolitti and G. Tavanti reported that in the cementation of steel by gases, say ethylene at 1050°, the curves showing the concentration of carbon at different depths below the surface of the metal show a step with about 1·2 per cent. of carbon, and the phenomena was regarded as an effect of liquation. A. Bramley and co-workers were unable to verify this observation.

H. Caron observed that besides barium carbonate other carbonates, e.g. those of strontium, lithium, sodium, potassium, etc., favour the cementation of iron and steel. F. Hebler found that no better results were obtained by wood-charcoal than with other carbonaceous materials, and that the degree of cementation is scarcely affected by the addition of chalk to the carbon, but the thickness of the hardened layer progressively increases by the use of the carbonates of sodium, strontium, and barium. The subject was studied by J. Herbert. The explanation of F. Giolitti, A. R. Page, J. F. Shadgen, and J. Tetschenko-Tschopiwsky assumes that the effect is due to the decomposition of the carbonate and the conversion of the carbon dioxide into the monoxide. H. Rodman, however, thought that the carbon monoxide so produced is less important than the residual oxide. G. Takahashi found the carburization of iron or steel in the presence of carbon is more energetic in the presence of the carbonate than it is in the presence of a brisk current of carbon monoxide ; that the carbonate may accelerate the action even when it has not suffered dissociation ; that in a current of carbon monoxide the carbonate accelerates the carburization process even in the absence of solid carbon ; and that the formation of carbon monoxide by the direct reaction between the carbonate and solid carbon is not the main factor involved in the process. He assumed that the carbonate separates carbon from carbon monoxide ; that the velocity of carburization increases as the amount of separated carbon coming in contact with the surface of iron or steel increases ; and that any substance which favours the separation of carbon from carbon monoxide accelerates the speed of carburization. The carbon liberated from carbon monoxide easily reacts with carbon dioxide. The carbonates do not energize the process of carburization if no carbon monoxide is present. The active carbon liberated from carbon monoxide diffuses readily into iron and steel. The energizing action of the carbonates is therefore due to the separation of active carbon by a reaction between the carbonates and carbon monoxide and the subsequent diffusion of this carbon into the iron or steel.

H. W. B. Roozeboom used the phenomenon of the formation of free cementite in the direct carburization of cementite against the hypothesis that cementite is metastable at the temp. of cementation ; but G. Charpy and P. Pingault found that the cementite is relatively stable—vide infra—and F. Osmond, G. Charpy, and C. Benedicks showed that the cementite may be formed by the oscillations of temp. which are inevitable during industrial cementation. The cementite separates during the cooling alternation of temp. The results were confirmed by F. Giolitti and G. Scavia. They showed that there is a difference in the rate of the dissolution of cementite in γ-iron and the rate at which carbon dissolves in iron by cementation. The iron carbide set free during the cooling is in a form best adapted for rapid dissolution in the iron. In the heating phase carbon is dissolved—as cementite—by cementation, and cementite also passes into soln.

In the cooling phase cementite separates out again. As a result, when there is an oscillation of the temp., there is an increase in the carbon present in the cemented zone above the value corresponding with the conditions of equilibrium realized when the temp. is constant. The phenomenon is complicated by the speed of dissociation of carbon monoxide during the lowering of the temp., the speed of diffusion of the gases in iron at different temp., the speed of the reaction of the carbon of the solid soln. on the mixtures of carbon monoxide and dioxide, at various concentrations and temperatures, etc.

A. Bramley and A. J. Jinkings showed that in the cementation of iron and steel with carbon monoxide the rate of flow of the gas affects the weight of carbon introduced, but not the depth of penetration of the carbon. The period of carburization affects the weight of carbon introduced, and if the carburizing period increases in geometrical progression, the depth of penetration also increases in this way, but with a different common ratio. The amount of carbon absorbed increases continuously with a rise of temp. between 800° and 1000°; the depth of penetration also varies, increasing in a linear manner with rise of temp. The concentration-depth curves are steeper the lower the temp. The weight of carbon introduced diminishes uniformly with an increase in the original conc. of the carbon. A steel with 1·54 per cent. of carbon cannot be further carburized by carbon monoxide at 950°. The concentration-depth curves are flatter the higher is the initial conc. of the carbon in the steel. The depth of penetration of the carbon being independent of the rate of flow of the gas and of the initial conc. of the carbon, the depth to which the carbon penetrates at constant temp. and press. is independent of the gradient of the carbon concentration.

A. Bramley and G. H. Beeby likewise studied the cementation of steel with the nitrogenous vapours of pyridine or methyl cyanide in a current of carbon monoxide. The efficiency of methyl cyanide increased progressively up to 1100°, but pyridine became less efficient above 1000°. The conc. of carbon in the cemented zone when methyl cyanide was used, was increased by a rise of temp., but the conc. of nitrogen was decreased. In the case of pyridine, an increase of either the period or temp. of cementation causes the conc. of both nitrogen and carbon to rise to a maximum and then fall again. The maximum with nitrogen was attained at a lower temp. than with carbon.

Fig. 75.—Depth of Penetrations of Carbon with Carbon Monoxide associated with Pyridine, Ammonia, and Methyl Cyanide.

A. Bramley and G. Turner obtained results analogous to those obtained with pyridine by adding ammonia to the carbon dioxide. A comparison of the results is shown in Fig. 75. They found that the carburizing action of the mixtures of carbon monoxide and different proportions of ammonia is much greater than that of carbon monoxide alone. The stimulating action of ammonia is attributed partly to the formation of cyanides and partly to the influence of the hydrogen formed by the decomposition of the ammonia on the carbon monoxide and carbon dioxide equilibrium. The distribution of nitrogen in the cemented zones resembles closely that which results from cementations made with mixtures of carbon monoxide and methyl cyanide, but the way in which the carbon is distributed resembles more the effect produced by pyridine. Mixtures of carbon monoxide and hydrogen have stronger carburizing properties than carbon monoxide itself, but not so intense as the corresponding mixtures containing ammonia.

A. Bramley and G. Lawton studied the carburization of steel with the vapours of hydrocarbons—xylene, toluene, benzene, and petrol—along with carbon monoxide or nitrogen. They found that the depth of penetration of the carbon increased according to a linear law as the temp. of cementation was raised; as the

period of cementation was increased in geometrical progression, the depth of penetration increased in the same way, but with a different common ratio ; the depth of penetration was not much affected by the rate at which the carburizing gas mixture was passed through the furnace, but it appeared to be slightly greater the stronger the cementing agent used. This is not in agreement with A. Bramley and A. J. Jinkings's experiment, where the hydrocarbon was carried into the cementation chamber by means of nitrogen ; it was found that uneven carburization was produced under the same conditions as yielded uniformity when carbon monoxide was used as the vehicle for introducing the hydrocarbon vapour. A. W. Machlet cemented steel with propane and air under press.

A. Bramley and H. D. Lord showed that after bars of the same steel, carburized to the same extent initially, had been reheated for a definite period at the same temp., but in atmospheres differing greatly from one another, the redistribution of carbon was the same in all cases. This result is taken to support the solid diffusion theory, and to be incompatible with the gaseous diffusion theory. A slight loss of carbon occurred in all cases when the carburized steels were reheated.

The cementation of iron with the gas under pressure was studied by F. C. Langenberg ; with cyanogen, by W. J. Merten, and E. Pérot ; with cyanamide, by P. W. Shimer, E. Pérot, and H. Fay ; with cyanides, by E. F. Davis, B. Jousset, A. H. d'Arcambal, V. E. Hillman, F. Rapatz, H. B. Northrup, and G. R. Brophy and S. B. Leiter—*vide infra*, nitridization of iron ; with ammonium formate, by H. Reininger ; with fused sodium carbonate, by W. A. Jayme ; with methane, or a mixture of hydrogen and methane or natural gas, by W. P. Sykes, and F. Eisenstecken ; with blast-furnace gases, by T. H. Byron ; and with coal gas, by W. Rohland, O. J. Wilbor and J. A. Comstock, and R. G. Guthrie and O. Wozasek. P. Pingault observed that sodium cyanide does not cement iron at temp. up to 900° when air is absent, whilst grey cast iron heated with sodium cyanide at 675° shows an outer zone from which all the carbon has been burned away. If fused sodium cyanide be electrolyzed at 650° with soft steel electrodes, the anode with a high enough current density gives indication of cementation. The effect of dissolved or included oxides was studied by E. W. Ehn, and S. P. Rockwell and F. Downes, H. W. McQuaid and E. W. Ehn.

The observations of P. Oberhoffer and E. Piwowarsky, A. Vita, E. Mauer, and K. Iwase show that the amount of gas which can be absorbed by iron and steel is very small, being only 0·05 grm. per 100 grms. at 1000°. This, said G. Takahashi, is far too small to explain the observed rate of penetration of carbon into iron, and he favours the hypothesis that the carbon monoxide, hydrocarbons, and cyanide do their work by decomposing on the surface of the iron, and the principal mechanism of carbon penetration is attributed to the diffusion of the nascent carbon atoms into the body of the metal. If the carburization be effected by an agent of the carbon monoxide system, or of the hydrocarbon system under the same conditions, the distribution of the carbon is the same with different agents irrespective of their difference in efficiency.

L. Guillet studied the cementation of **nickel-steels,** and, as previously indicated, he measured the speed of penetration of carbon, and showed that when 7 per cent. of nickel is present it is possible to obtain at the periphery a superficial zone with over 1 per cent. of carbon, which, when not tempered, but allowed to cool slowly, possesses the martensite structure and the hardness characteristic of tempered steels. By prolonging the carburization until the periphery has 1·5 per cent. of carbon, there is formed on the martensitic zone a superficial layer containing γ-iron, which can be polished without loss. F. Giolitti and F. Carnevali also studied this subject, and found that, other things being equal, (i) the course of the cementation with steels containing 2 to 3 per cent. of nickel is virtually the same as that of carbon steels ; (ii) when the proportion of nickel exceeds 3 per cent., the maximum concentration of carbon in the cemented zones decreases

with an increase in the proportion of nickel in the steel; (iii) the variations in the concentration of carbon in the cemented zones are more uniform in nickel steels than in carbon steels, and the phenomenon of liquation in the solid soln. is less intense than with carbon steels; (iv) in pearlitic nickel steels the region of transition from the hypereutectoidal to the eutectoidal layer in the cemented zone corresponds to a carbon content of 0·60 to 0·65 per cent., which is lower than the corresponding eutectoidal zone of cemented carbon steels with 0·9 per cent. of carbon; (v) the specific action of carbon monoxide in the cementation of nickel steels is the same as it is with carbon steels; and (vi) the speed of cementation, that is, the depth attained by the carburized zone in a given time with carbon and carbon monoxide, is slightly higher for nickel steels than it is for carbon steels. W. T. Griffiths, J. N. Greenwood, J. G. R. Woodvine, and S. C. Spalding discussed the cementation of nickel steels.

L. Guillet measured the speed of penetration of carbon in the cementation of **manganese steels**—*vide supra*. In general, manganese steels behave like nickel steels, except that on cementing a steel with, say, 5 per cent. of manganese, so that the external layer contains 1 per cent. of carbon, a pearlitic core is obtained, then a little martensite, and the periphery is characterized by a great abundance of troostite. It is not therefore as hard as steel with 7 per cent. of nickel. S. C. Spalding, and A. A. Blue also made observations on the subject. L. Guillet, and S. C. Spalding measured the rate of penetration of carbon in **chromium steels**—*vide supra*. When a steel with 5 per cent. of chromium is cemented, a martensitic steel can be obtained, and, by sufficiently extending the operation, there is formed in the surface layer a complex iron-chromium carbide. G. Charpy's observations, supplemented by those of F. Giolitti and F. Carnevali, are indicated above. F. Giolitti and F. Carnevali also found that the cementation of a steel with 2·33 per cent. of chromium, with ethylene, carbon monoxide, or carbon and carbon monoxide, is similar to that with carbon steel. In general, however, the presence of chromium tends to increase the maximum concentration of the carbon in the cemented zones. L. Guillet, and S. C. Spalding measured the rate of penetration of carbon in **molybdenum steels,** and also in **tungsten steels** —*vide supra*. The cementation of tungsten steels produces the double carbide, or increases the proportion in which it already exists. L. Guillet, and S. C. Spalding measured the rate of penetration of carbon in **silicon steels**—*vide supra*. Steels with over 7 per cent. of silicon, or those with a smaller proportion if heated a sufficiently long time, contain all the carbon in the state of graphite, and they cannot be cemented. L. Guillet measured the rate of penetration of carbon in **titanium steels,** and also in **aluminium steels**—*vide supra*. E. W. Ehn studied the action of dissolved oxides on the case-hardening of steels; H. Lüpfert, the heat treatment of case-hardened steels.

Experienced workmen accustomed to particular types of steel and to a particular process of cementation can arrange bars of cemented steel into groups roughly in accord with their carbon contents. Their judgment is based on the appearance of the fracture. The bars of cemented wrought iron do not have the metallic appearance and the uniformity presented by the original bars. They are rather coarsely opaque, brown in colour, and covered with bubbles, blisters, or beads varying in size from a pea to a walnut. It is considered a good sign when the blisters are small, regular, and uniformly distributed over the surface of the bars and do not accumulate along definite lines. The characteristic blisters have given rise to the name applied to the cemented bar—**blister steel,** *acier poule,* and *Blasenstahl.* H. M. Howe and A. Sauveur, for instance, say that blister steel is defined as steel obtained by carburizing wrought iron, or steel of low carbon content, by heating it in contact with substances rich in carbon; and they apply the term to steel obtained by cementation whether or not it shows the characteristic blisters. Another characteristic is the variation in structure from the periphery to the centre of the mass. This gives an indication of the approximate progress of the cementa-

tion. Analyses were reported by J. O. Arnold, H. Wedding, A. Ledebur, O. Thallner, J. Percy, C. W. Bildt, etc. The blistering does not generally appear in the partial cementation of cast-steel objects—e.g. case-hardening. J. Percy first suggested that the blisters are formed by the local evolution of carbon monoxide formed when carbon diffuses into iron containing oxides and slags. If carbon monoxide and not the diffusion of carbon is responsible for the carburization of iron, this hypothesis requires modification. J. Percy later showed that if slag is not present in the iron, the blisters are not produced, although cementation proceeds as usual. The slag is therefore responsible for the blisters. W. Siemens also observed no blistering in the cementation of mild steel. T. H. Henry supposed that the blisters are produced by carbon disulphide formed by the action of carbon on the sulphides in the metal.

The manufacture of **cement steel**—*acier cémenté* (French), *acciaio cementato* (Italian), *acero cementado* (Spanish), *Cementstål* (Swedish), and *Zementstahl* (German)—by fusing in crucibles—**crucible steel**—wrought iron which had been first carburized by cementation was inaugurated in Sheffield about 1740 by B. Huntsman.[2] This furnished a sounder and more homogeneous product than had previously been obtained. This process gave a strong impetus to the manufacture of crucible steel. On account of the relatively large expenditure of time and fuel in preparing crucible steel from carburized wrought iron, other methods have been proposed. The processes of S. Lucas,[3] W. E. Newton, A. Chenot, etc., were discussed by J. Percy, E. Grateau, S. Kern, and W. Metcalf.

According to F. Giolitti,[4] the steel obtained by fusing wrought iron, carburized by cementation, is superior to the crucible steel now made by directly carburizing wrought iron during the fusion of wrought iron melted in covered crucibles in which the desired amount of carbon is placed on the charge or the mixture is heated in the electric furnace ; or the steel obtained by cementing the best Bessemer or Siemens-Martin soft steels and melting the product in a crucible.

F. G. Bates,[5] A. A. Ackermann, and J. Lecarme tried to produce alloy steels by mixing a compound of the required metal with the cementation powder. F. Giolitti added that the technology of the direct manufacture of special steels by means of the so-called processes of *metallic cementation* is in its infancy and has not yet given satisfactory practical results. H. Moissan attempted to cement iron with *silver* and *chromium* ; and J. Cournot, and A. Folliet and N. Sainderichin, with *aluminium*. J. Laissus embedded steel in powdered ferrochromium and obtained, at carburizing temp., a thin coat of high chromium steel; and similarly in the presence of ammonium chloride he obtained, at 800° to 1200°, another case or layer of high *molybdenum, tungsten*, or *tantalum steel*. T. Miyaguchi embedded the iron or steel in a mixture of carbon and boric oxide, and obtained a hard, tough layer of borized metal ; *boron* was also examined from this point of view by N. Tschischewsky, T. P. Campbell and H. Fay, M. Fesczenko-Czopowse, and J. Fetschenko-Tschopiwsky ; and aluminium by A. B. Kinzel. H. Moissan found that if soft iron be embedded in *silicon* and heated sufficiently, the metal is silicized. J. E. Stead obtained no silicon penetration at 1125° to 1175°, and fusion occurred at 1300° to 1350°. W. E. Thomson obtained no penetration with silicon at 1100°, superficial penetration between 1100° and 1350°, and fusion at higher temp. P. Lebeau observed a penetration of silicon in reduced iron at 950°. A. Sanfourche studied the silico-cementation of steel by silicon chloride ; and W. E. Vawter obtained a coating of silicon on iron heated in silicane at 400° to 600°. The coating easily flaked off. R. T. Haslam and L. E. Carlsmith obtained silicon penetration by heating the metal in ferrosilicon between 800° and 1200°, where fusion generally occurred. Confirmatory results were obtained by A. Fry, L. Guillet, and E. G. Mahin and co-workers. W. van Drunen obtained surface films of chromium-nickel-iron by the simultaneous diffusion of chromium and nickel into iron.

§ 11. The Preparation of Purified Iron

The term iron is applied not only to the element supposed to be chemically pure, but it is also employed generally for various forms of technical iron and even for steel—*vide supra*, nomenclature. In speaking of iron, therefore, it is often necessary to designate the particular kind of iron to which reference is made. A close approximation has been made to chemically pure iron, but it is doubtful if strictly pure iron has ever been made *en masse*. Some investigators of the magnetic properties of iron are dissatisfied with iron of the highest degree of purity that they have been able to prepare. A great many determinations of the properties of iron have been made with Swedish charcoal iron, since this iron was for a long time one of the purest forms of iron in commerce. O. Ruff and E. Gersten found that it approximated to the following analysis:

Fe	C	Mn	Si	P	S	Cu
99·745	0·085	0·090	0·020	0·046	0·004	0·010 per cent.

Iron of a high degree of purity is manufactured by the open-hearth process for steel as modified by R. B. Carnahan.[1] The product, prepared by the American Rolling Mill Co., is known commercially as *armco iron*. W. J. Beck gave the first of the following analyses, and R. L. Keynon the second:

Fe	C	Mn	Si	P	S
99·865	0·013	0·021	trace	0·005	0·035 per cent.
(99·941)	0·013	0·017	trace	0·005	0·025 per cent.

So that, as pointed out by A. Sauveur, it rivals electrolytic iron in its degree of purity, and it is much cheaper. The subject was discussed by A. S. Cushman, R. L. Keynon, E. L. Dupuy, W. J. Beck, and J. A. Aupperle. The process of manufacture is thus described by R. B. Carnahan:

The basic open-hearth furnace is charged with low carbon or steel scrap. Lime or limestone is added to the charge to reduce the sulphur and phosphorus, these agents being preferably charged prior to charging the metal. The charge is then refined, as in making soft steel, by the employment of ore or agitation, or both, but recarburization at this stage is not necessary in case the charge melts to a product specially low in carbon. Carbon, manganese, sulphur, and phosphorus are thereby reduced. This refining operation is carried out for a much longer time, from one to four hours more, than is usually employed in making high-grade soft steel; naturally, while the carbon is being more and more reduced, the m.p. of the iron bath rises and the temp. must be gradually raised, until it is finally at least 1565°. The refining operation is finished when the bath contains not over 0·14 per cent. of sulphur, phosphorus, carbon, manganese, and silicon taken in the aggregate. For the best results it is desirable and practicable to reduce this aggregate to less than one-half the percentage named, and to have neither carbon nor manganese over 0·02 per cent. The refined metal is poured into moulds while still at a high temp.; and, while still molten, it is deoxidized and degasified by the addition of aluminium to the molten metal—say 2½ lbs. per ton. If this operation be conducted in the furnace, aluminium pig-iron is employed. Aluminium may be economized by partially deoxidizing the bath by employing pig-iron—say 2 to 8 per cent. of the charge. The degasifying and deoxidizing agents must, of course, not be such as to lessen the above-mentioned purity of the ultimate product. The slag is floated off in tapping the metal.

Iron of a high degree of purity—*ferrum reductum*—has been prepared in the laboratory by reducing the purified ferrous or ferric oxides or salts. The reduction of the oxides by hydrogen has been discussed in a previous section, and the metal was obtained in this way by J. J. Berzelius,[2] A. Thibierge, E. Soubeiran and J. B. Dublanc, A. M. B. Burin du Buisson, H. F. Gaultier de Claubry, S. de Luca, M. H. Deschamps, and L. Dusart. H. Moissan, and F. Glaser thought that the reduction occurs in definite stages, but S. Hilpert, L. Mathesius, and K. Hofmann showed that this is not the case, for there is a continuous gradation in the composition of the solid phase between oxide and metal. F. Wüst and P. Rütten observed that the reduction can be observed at as low a temp. as 350°, but S. Hilpert, with artificial ferric oxide, and F. Wüst and P. Rütten, with the natural oxide, found that the temp. at which reduction begins depends on the previous history of the oxide. F. Wüst and P. Rütten also showed that the speed of reduction depends on the porosity and gas permeability of the oxide. G. P. Baxter and C. R. Hoover showed that in order to obtain iron of a high degree of purity, a much higher temp., 900°, is needed for the reduction than that at which the reduction begins. H. Moissan stated that the reduction is completed in 36 hrs. at 350°, in 12 hrs. at 440°, and at 500° the reaction proceeds very quickly. The equilibrium conditions are discussed elsewhere. F. Wöhler reduced crystalline ferric oxide prepared by heating a mixture of one part of ferrous sulphate and 2 or 3 parts of sodium chloride and leaching the product with water; while A. Matthiessen and S. P. Szczepanovsky heated a mixture of equal parts of ferrous sulphate and dehydrated sodium sulphate to redness in a platinum crucible until sulphurous fumes were no longer evolved, extracted the mass with water, reduced the oxide with hydrogen, and fused it to a regulus in a lime crucible in the oxyhydrogen flame.

According to L. Jordan and co-workers, crucibles made from commercial fused oxides, alumina, zirconia, and magnesia, were unsuitable for melting pure iron, the alumina and zirconia because of the contamination of the melt by silicon and the magnesia because of sulphur. Strong and dense crucibles can be made from calcined, chemically pure magnesia mixed with 2 per cent. of magnesium chloride and about 10 per cent. of water, and such crucibles fired to about 1600° enable pure melts to be obtained. Magnesia crucibles bonded with shellac and alcohol are also satisfactory, and materials found suitable for melting pure iron were satisfactory also for nickel.

With the idea of removing traces of sulphur, phosphorus, silicon, and occluded hydrogen, M. Crolas removed sulphates from ferric chloride by barium chloride, purified the chloride by recrystallization, and then converted the chloride to oxide for reduction with hydrogen. H. Kreusler converted purified Mohr's salt to oxalate, converted the oxalate to oxide by heating it over an ether flame, and reduced the oxide in a hard glass tube with purified electrolytic hydrogen. A. Sanfourche, L. C. Turnock, N. Parravano and P. de Cesaris, Vereinigten Stahlwerke, and O. Ruff and E. Gersten also purified the oxide before reducing it with hydrogen. T. W. Richards and G. P. Baxter dissolved electrolytic iron in purified conc. nitric acid, and after recrystallizing the nitrate a few times, treated the soln. with aq. ammonia. The washed and dried hydroxide was heated in a porcelain tube at 900° in a current of purified electrolytic hydrogen for 20 hrs. F. K. Bell and W. A. Patrick recommended heating the nitrate in hydrogen at 600° for 7 hrs. and then one hour at 1000°; and G. P. Baxter and C. R. Hoover recommended heating the nitrate in air at 1000°, until its weight is constant, and then reducing the oxide in hydrogen at 1100° to 1150°. The process was also used by T. W. Richards and co-workers, and G. P. Baxter and co-workers. T. W. Richards and G. P. Baxter recommended the following process:

A soln. of commercial " chemically pure " ferrous chloride was treated with an excess of hydrogen sulphide, and the resulting sulphides and sulphur were removed by filtration. From the filtrate, after oxidation with nitric acid, the iron was precipitated with an excess of aq. ammonia and the precipitate was thoroughly washed by decantation. In this

process traces of a number of metals which might have been present must have been removed. The precipitate was dissolved in sulphuric acid, and by cautious addition of aq. ammonia basic ferric sulphate was thrown down ; a precipitate which is more easily washed than ferric hydrate, but which was re-dissolved in sulphuric acid with considerable difficulty. In order to reduce to the ferrous state the ferric sulphate thus formed, the soln. was next subjected to the action of a galvanic current of several ampères. The soln. was contained in a large platinum dish which served as the negative electrode, the positive electrode being a flat spiral of platinum wire. Since the soln. was very conc. and contained a considerable excess of sulphuric acid, the greater part of the ferrous sulphate crystallized out when the soln. was allowed to cool. By alternately electrolyzing and cooling, almost all of the iron was eventually obtained as ferrous sulphate. The ferrous sulphate was then mixed with purified ammonium oxalate and the soln. electrolyzed—aluminium remains in soln., and manganese is deposited as peroxide on the anode. The iron was then dissolved in nitric acid and treated as before.

E. Péligot reduced ferrous chloride at a red-heat in hydrogen and obtained crystals of iron—for crystals, *vide infra.* W. Spring added that crystals of iron are formed if the reduction occurs at a high enough temp. F. Schmitz found that at 300° to 400° the reduced metal is pulverulent ; and H. Wolfram observed that the reduction is very slow at 220°, and the black product contains chlorine. A. B. Bagdasarian showed that the reduction of ferric chloride occurs in two stages : $FeCl_3 \rightarrow FeCl_2 \rightarrow Fe$. The reaction was studied by K. Jellinek and R. Koop. For the equilibrium conditions, etc., *vide infra,* ferrous chloride. F. Wöhler, G. Dragendorff, L. Mond and C. Langer, and D. Guicciardi similarly reduced dried ferrous oxalate in hydrogen ; and C. Stahlschmidt, iron nitride. The reduction of the complex cyanides—used as catalysts in formation of ammonia from a mixture of hydrogen and nitrogen at 360° to 430° and 80 to 95 atm. press.—to form a-iron was observed by A. Mittasch and E. Kuss ; and R. Brill and H. Mark, and A. Mittasch and co-workers showed that ferrous cyanide is probably formed as an intermediate stage in the reduction.

B. Lambert and J. C. Thomson heated ferric nitrate in an iridium boat so as to form ferric oxide or a basic nitrate. The product was placed in a vitreous silica tube, and heated just above 1000° in a current of hydrogen obtained by the electrolysis of a soln. of barium hydroxide. T. W. Richards and G. P. Baxter tried an analogous process, and said that when the nitrate is heated in platinum vessels, the metal always contained a trace of platinum, which remained as a residue when the product was dissolved in acid. According to F. Sauerwald, commercial ferrum reductum is usually contaminated with foreign matter. The impurities in iron prepared by reducing the purified oxide or chloride are oxide and occluded hydrogen. G. P. Baxter said that the hydrogen can be removed by melting the iron in vacuo ; and H. Kreusler added that one fusion in vacuo is not sufficient. A. Sieverts said that only 0·0002 per cent. of hydrogen is occluded at 800° ; and G. P. Baxter and C. R. Hoover showed that even if the metal is cooled in hydrogen, the occluded hydrogen is not sufficient to affect appreciably the value obtained for the at. wt. T. W. Richards and G. P. Baxter observed that small quantities of oxygen are present in iron reduced from the oxide in hydrogen at 900°. The presence of the oxide was also noted by F. Mylius, R. Schenck and T. Dingmann, and R. Ruer and J. Kuschmann—*vide infra,* ferrous oxide. Iron oxide can also be reduced to the metal by using carbon monoxide in place of hydrogen. As shown by R. Akerman and C. G. Särnström, L. Gruner, A. Guntz, S. Hilpert, H. Moissan, and K. Stammer, the product is liable to be more or less carburized—*vide supra.* A. Ledebur, L. Mathesius, and R. Schenck and T. Dingmann showed that the reduction must be conducted at a low temp., since carburization is to be avoided. The reactions are then symbolized : $Fe_3O_4 + CO \rightleftharpoons 3FeO + CO_2$; and $FeO + CO \rightleftharpoons Fe + CO_2$.

Iron pentacarbonyl, prepared by L. Mond and co-workers, was shown by M. Berthelot and G. André, and A. Stoffel to decompose when passed through a hot glass tube, depositing a thin film of iron as a mirror on the glass. A. Mittasch observed that the decomposition of the pentacarbonyl begins at about 60°, and,

at ordinary press., is completed at 200°.   The subject was studied by H. Freundlich and co-workers, the Farbenindustrie A.G., and A. Curs—*vide* **5**. 39, 27. A. Mittasch showed that it is possible to prepare iron from the carbonyl spectroscopically free from sulphur, phosphorus, and arsenic, copper, zinc, silicon, manganese, nickel, and cobalt ; and that carbon and oxygen are alone present as impurities—possibly in the form of ferrous oxide and iron tritacarbide—*vide infra*, pyrophoric iron.   A. E. van Arkel observed that metals which form an easily-dissociated compound can be obtained in a coherent form by heating a filament of the metal in an atm. of the vapour of the compound.

A. Hiorth observed that the oxide is reduced by heating it in sodium vapour ; and F. Ephraim, that the oxide or phosphate is reduced to metal by heating it with sodium amide.   J. A. Poumarède reduced ferrous chloride by heating it in the vapour of zinc.   F. M. Perkin and L. Pratt found that iron oxide is reduced to the metal when it is heated with calcium or calcium hydride at a bright red-heat. Z. Roussin found that magnesium precipitates iron from slightly acid soln. of ferrous and ferric salts ; some hydrogen is also evolved.   A. Commaille found that magnesium precipitates hydrated ferrous oxide from a neutral soln. of ferrous sulphate, and iron from an acidified soln.   H. Goldschmidt also observed that the oxide is reduced to metal by heating it with aluminium as in the alumino-thermite process ; and L. Weiss and O. Aichel, that the oxide is similarly reduced by mischmetal.   According to H. Capitaine, and G. E. Davis, boiling aq. soln. of ferrous salts are reduced by zinc, yielding finely-divided iron.   According to N. W. Fischer, and J. A. Poumarède, if zinc be immersed in a neutral soln. of ferrous chloride or sulphate, in a stoppered bottle, iron contaminated with much oxide is precipitated, but E. F. Anthon added that he obtained only flakes of hydrated ferrosic oxide— presumably air had access to the soln. in the latter case.   H. Capitaine found that when a plate of zinc and copper, soldered together, is immersed in a neutral soln. of ferrous chloride, a friable mass of iron is deposited on the copper, and it becomes tough when heated in hydrogen.   O. Prelinger observed that powdered manganese reduces iron from a soln. of ferrous sulphate.   G. Gore found that a neutral soln. of ferrous sulphate deposited no iron on copper, silver, gold, brass, tin, lead, antimony, bismuth, nickel, german silver, or platinum.   J. H. Gladstone and A. Tribe observed that a platinum-iron couple reduces ferric to ferrous salts more rapidly than does iron alone ; platinum alone has no action.   F. M. Raoult observed no precipitation of metal from acidic or neutral, cold or hot soln. of salts of iron by a gold-iron couple. W. Ipatieff and W. Werchowsky found that if soln. of iron salts be heated in hydrogen under press., oxide and a basic salt are deposited, but with a 0·1N-soln. of iron acetate at 400°, in hydrogen at 420 atm. press., a small proportion of spongy iron separates out.

M. Zängerle, and W. Engelhardt obtained the metal by heating ferrous oxalate with a mixture of potassium ferrocyanide and carbonate, and extracting the product with water ; and A. Brochet, by heating ferrous formate in a closed vessel. C. Broling tried to purify iron by melting iron filings with a quarter of their weight of smithy scales under a layer of green glass in a luted crucible at a high temp. ; and L. Troost, by heating iron in a lime crucible by means of an oxyhydrogen flame, finishing off with the flame strengthened with oxygen—the oxidized impurities are absorbed by the crucible.

According to A. C. Becquerel [3] the electrolysis of a conc. soln. of ferrous sulphate or chloride results in the deposition of small granules of iron on the negative platinum ; with sodium chloride, separated from the soln. of ferrous salt by moist clay, glittering crystals of iron are deposited, and they exhibit magnetic polarity. R. Böttger in 1846 also described the electrodeposition of iron, and later on observations were made by H. Krämer, and F. Varrentrapp.   In 1846, M. Boch-Buschmann and M. Liet prepared plates 2 mm. thick, and H. Meidinger in 1867 and H. Bouilhet in 1868 prepared plates and galvanoplastic moulds of iron by processes which, according to L. Guillet, were secret.   In 1868, E. Klein and H. Jacobi prepared iron electrodes

for printing bank-notes in Russia. D. Belcher, S. O. Cowper-Coles, L. Guillet, W. E. Hughes, D. R. Kellog, and W. A. Macfadyen discussed the application of the electrodeposition of iron to the production of finished iron sheets and tubes in one operation, and the repair of worn parts of machinery.

According to F. Förster, neutral soln. of ferrous sulphate do not give good results as electrolyte for the electrodeposition of iron, since at ordinary temp. the resistance is high and disturbances are caused by the liberation of hydrogen at the cathode. The need for the employment of high current densities favours the liberation of hydrogen at the cathode. This makes the deposit brittle and hard. With low current densities, at low temp., the deposition is slow, but the contamination with occluded hydrogen is relatively small. These conclusions were established by the work of H. Lee, S. Maximowitsch, A. Müller, and A. Ryss and A. Bogomolny. A. Watt observed that the results are better if the temp. of the bath be raised to 60° or 70°. F. Förster said that with the simple sulphate the best working temp. is 80°; A. Pfaff gave 70°; and W. A. Macfadyen found 65° gave the best results with Mohr's salt—ammonium ferrous sulphate. The increased temp. lessens contamination with occluded hydrogen and enables high current densities to be employed. Observations were also made by M. Schlötter, and G. Tischtschenko and H. Plauson. The electrolysis of neutral soln. was discussed by E. F. Kern, S. Pagliani, and A. Skrabal. According to G. Langbein, if the bath tends to become acid, a few linen bags containing magnesium carbonate can be suspended in the liquid ; and if the bath becomes alkaline, the deposit acquires a matt appearance and is liable to peel off—in that case a few drops of dil. sulphuric acid or, better, citric acid will restore neutrality. The subject was discussed by N. H. M. Dekker, O. Mustad, F. Förster, S. Maximowitsch, A. S. Ramage, and C. J. Reed. F. Förster added that better results are obtained by working with a bath slightly acid. This prevents the hydrolysis of the electrolyte, and lessens the contamination of the cathode deposit with occluded hydrogen, which makes the iron brittle and hard. Acetic or oxalic acid gives satisfactory results. A. Skrabal used dil. sulphuric acid in a bath of ammonium ferrous oxalate ; A. Pfaff, and H. Lee, dil. sulphuric acid in a bath of ferrous sulphate free from ferric salt ; F. Förster, and O. Mustad, boric acid in a soln. of ferrous sulphate ; T. Moore, metaphosphoric acid in a soln. of ferric sulphate and an excess of ammonium carbonate.

The use of ferrous sulphate alone is not usually recommended, since the bath is liable to become turbid soon after it has been in use. F. Varrentrapp therefore recommended the addition of ammonium salts to the electrolyte. This, said F. Förster, keeps down the conc. of the OH'-ions in the vicinity of the cathode and thus prevents the deposition of ferrous hydroxide. K. Arndt, T. P. Thomas, A. Pfaff, and H. Lee recommended the addition of ammonium sulphate; and A. Hiorns, A. Skrabal, R. Amberg, A. Müller, E. Klein and H. Jacobi, C. F. Burgess and C. Hambüchen, W. C. McWilliams, A. Neuberger, A. Ryss and A. Bogomolny, C. H. Desch and E. M. Vellan, W. H. Gee, D. Belcher, W. E. Hughes, G. Gore, W. H. Walenn, and S. A. Tucker and E. Schramm recommended using ammonium ferrous sulphate. W. A. Macfadyen found that thick, adherent deposits of iron on a steel base could be readily obtained from dil. soln. of ferrous ammonium sulphate at ordinary temp., but the deposition proceeds slowly. With conc. soln. equally good results were produced at about seven times the speed obtained with dil. soln. The deposits were very sensitive to the acidity of the soln. ; an acidity of $0.005N$-H_2SO_4 gave the best results. With a temp. of 50° deposition from a conc. soln. occurred about fifty times as rapidly as with a cold, dil. soln. The yield is 90 to 95 per cent. of the theoretical with a soln. containing 50 to 100 grms. of Mohr's salt per litre and acidified to $0.005N$-H_2SO_4, using a current density of 0.86 to 2.48 amps. per sq. dm. The purification of iron by electrodeposition from a bath of Mohr's salt was described by R. Amberg, S. O. Cowper-Coles, W. M. Johnson, H. Lovelock, A. Müller, and W. Palmaer and J. A. Brinell.

The addition of ammonium chloride to the ferrous sulphate bath—say 1 : 2—

has been recommended by R. Böttger, C. F. Burgess, A. Hiorns, E. Klein and H. Jacobi, H. Krämer, R. Lenz, G. F. McMahon, W. Pfanhauser, N. B. Pilling, F. A. Shepherd, B. Speed and G. W. Elmen, B. Stoughton, F. Varrentrapp, and T. D. Yensen. The addition of sodium sulphate to the ferrous sulphate bath in order to increase the conductivity of the soln. was recommended by M. Schlötter, and E. F. Kern; P. A. Govaerts and P. M. Wenmaekers added sodium thiosulphate and enough organic acid to produce an incipient decomposition of the thiosulphate. Small potential differences may be used and thick, strongly adherent deposits of iron obtained. Langbein-Pfanhauser Werke, and F. Fischer added sodium chloride to the ferrous sulphate bath; and A. Boucher, and Société de Fer Grenoble, ferrous chloride—O. P. Watts and M. H. Li used a mixture of ferrous sulphate and ferrous chloride (150 : 75 grms.) and 6 grms. of ammonium oxalate (or 0·6 grm. of hexamethylene tetramine) per litre. C. Kadota recommended a soln. of ferrous chloride equivalent to 10 to 15 per cent. Fe; 12 per cent. sodium chloride; and 0·005 to 0·008N-HCl; and a current density of 3 to 7 amps. per sq. dm. at 85°.

The use of complex salts hinders the separation of iron hydroxide and raises the conductivity of the soln. This method was adopted by F. Varrentrapp in 1868. According to S. Maximowitsch, a very good method of preparing electrolytic iron is to make a soln. containing 20 per cent. of ferrous sulphate, $FeSO_4,7H_2O$, and 5 per cent. of magnesium sulphate, $MgSO_4,7H_2O$; and 25 grms. of sodium hydrocarbonate were dissolved in this soln. The skin of ferric hydroxide which forms on the surface protects the bath from further oxidation. The precipitate is allowed to settle to the bottom and to remain undisturbed; a wrought-iron anode and a copper cathode (thinly silvered and iodized) are used. The bath is kept continuously at work, and 20 to 25 grms. of sodium hydrocarbonate are added about twice a week. The iron formed improves in quality as time goes on, finally reaching a strength of 1580 kgrms. per sq. cm., and being so soft that it can be bent at a sharp angle without breaking. The best current density was found to be 0·3 amp. per sq. dm., and the current efficiency, 97 to 99 per cent. The brittleness commonly found with electrolytic iron is here absent, and this is attributed to the low acidity of the bath, which does not favour the occlusion of hydrogen. A. Ryss and A. Bogomolny found that both the magnesium sulphate and sodium hydrocarbonate are essential constituents of the bath, and that the best conditions are : current density, with a rotating cathode, 0·003 amp. per sq. cm. ; and an electrolytic bath of 200 grms. of ferrous ammonium sulphate or ferrous chloride, 50 grms. of magnesium sulphate, and 5 grms. of sodium hydrocarbonate per litre of water at a temp. of 15° to 18°. During the electrolysis, 4 to 5 grms. of sodium hydrocarbonate per litre are added at intervals of 3 days. The effects of various additions were tried, but no improvement in the deposit was observed. The addition of magnesium sulphate to enhance the conductivity of the ferrous sulphate soln. was favoured by E. Klein and H. Jacobi, W. C. Roberts-Austen, W. C. McWilliams, F. Haber, R. Amberg, C. F. Burgess and C. Hambüchen, W. Pfanhauser, O. Mustad, and V. Kohlschütter and H. Stäger. H. D. Hineline studied the electrodeposition of iron from a bath of iron sulphite and calcium sulphite.

According to A. Skrabal, iron of a high degree of purity is produced by using iron deposited electrolytically on platinum as the anode in a soln. of purified ferrous sulphate, as recommended by C. Stammer, or ferrous ammonium sulphate, as used by R. Böttger, H. Meidinger, etc., with a platinum foil as cathode and an e.m.f. of 0·4 volt. According to R. Amberg, and A. Müller, iron deposited from sulphate soln. is contaminated with sulphates—0·0050 to 0·0099 per cent. sulphur was found in iron from a sulphate bath, and 0·0024 to 0·0029 per cent. in iron from a chloride bath. When iron of a high degree of purity is to be prepared electrolytically, care must be taken to have an electrolyte of a high degree of purity. On the other hand, C. F. Burgess and C. Hambüchen, W. M. Hicks and L. T. O'Shea, H. Lee, and A. Skrabal observed virtually no sulphur in electrolytic iron; and with a conc.,

feebly acidic soln. of ferrous sulphate, at 70°, a current density of 2 amps. per sq. dm., and agitating the electrolyte by a current of gas, A. Pfaff observed only traces of sulphur in the electrodeposited iron ; for instance, with soln. acidified with 6, 12, and 13 per cent. of acid, the respective proportions of sulphur averaged 0·00030, 0·00065, and 0·00065 ; C. F. Burgess and C. Hambüchen obtained only 0·00018 per cent. of sulphur in electrodeposited iron ; W. C. Roberts-Austen, 0·005 ; J. O. Arnold, 0·15 ; O. W. Storey, 0·001 ; L. Guillet, 0·006 ; T. D. Yensen, 0·003 ; J. Billiter, 0·016 ; A. Vosmaer, 0·006 ; G. P. Fuller, 0·004 ; N. B. Pilling, 0·005 ; A. Bouchayer, 0·0048 ; and J. Escard, traces. According to A. Müller, the soluble anodes employed in the purification of iron should be as free from sulphur and carbon as practicable. L. Houllevigue found that with an anode of steel rapidly cooled from 900° the iron deposited on the cathode contained only 0·003 per cent. of carbon, whereas when the steel anode was slowly cooled, the cathodic iron had 0·033 to 0·035 per cent. of carbon. The subject was discussed by N. H. M. Dekker, H. Gerdien, W. A. Macfadyen, G. Masing, K. Oma, W. Pfanhauser, A. S. Ramage, and C. Tschappet. W. M. Hicks and L. T. O'Shea enclosed the anode of Swedish iron in a porous pot, to prevent the spongy carbon which separates from the anode reaching the cathode and interfering with the deposition. Any ferric hydroxide suspended in the electrolyte might interfere with the adhesion of the deposit if it settled on the cathode. Hence, in practice, deep tanks are used for the baths to allow the sediment to settle. A. Bouchayer, British Thomson-Houston Co., S. O. Cowper-Coles, F. Exner, and the Société Anonyme des Aciéries Firminy considered the rotation or oscillation of the anode during the electrolysis. E. Duhme prepared iron of 99·994 per cent. purity by the electrolysis of a cold sat. soln. of ferrous chloride containing magnesium chloride and free acid eq. to less than 0·01N. The anode may consist of steel or even cast iron. The cathode is rotated inside a stationary auxiliary cathode on which a small secondary alternating current (of which the negative component is greater than the positive) is superposed. A porous earthenware U-tube is arranged round the cathode and a current of air is blown through the tube. At the bottom of the cell a number of permanent magnets sealed into thin glass tubes serve to collect the particles of carbide and silicide that fall from the anode. V. Kohlschütter and F. Jakober found that the effect of superposing an alternating on the direct current is to lessen the percentage current-yield.

The electrodeposition of iron from soln. of ferrous or ferric chloride was studied by H. Buff, A. Geuther, W. Hittorf, H. Krämer, and J. Thiele. According to A. Ryss and A. Bogomolny, if ferrous chloride is electrolyzed—equal weights of water and of the salt—the temp. of the bath should be 60° to 70° ; the current density at the cathode should not exceed 0·004 amp. per sq. cm. ; rapid rotation of the cathode improves the quality of the deposit. E. Kelsen used a mixture of ferrous chloride, 122·5 grms. ; calcium chloride, 109 grms. ; potassium chloride, 110 grms. ; and water, 525 grms. Observations were also made by R. Amberg, D. Belcher, A. Boucher, C. T. Thomas and W. Blum, Chemische Fabrik Griesheim-Elektron, J. R. Cain and co-workers, T. P. McCutcheon and E. F. Smith, W. E. Hughes, H. Lee, S. I. Levy and G. W. Gray, E. Merck, R. H. Monk and R. J. Traill, A. Müller, A. Pfaff, A. Pertsch, W. Pip, A. S. Ramage, J. H. Paterson, M. Schlötter, O. Spinzig and A. Wannag, and G. Vié. According to W. A. Noyes, the minimum potential required for the electrolysis of an aq. soln. of ferrous salt is 0·66 volt at 20° when electrodes of electrolytic iron are employed ; this value decreases with a rise of temp., attaining a minimum at 110° ; a further rise of temp. is attended by an increased voltage. W. M. Hicks and L. T. O'Shea used a 5 per cent. soln. of ferrous chloride with enough ammonium chloride to make up the ratio $FeCl_2 : NH_4Cl = 1 : 2$. A clean copper plate was used as cathode, and a plate of Swedish iron in a porous cell as anode. A current density of 0·08 to 0·2 amp. per sq. dm. and 0·7 volt was used. The iron content of the bath should not fall below 4 per cent. $FeCl_2$. M. L. V. Gayler recommended the process for the preparation

of iron of a high degree of purity. The contamination of the deposited iron with chlorides was discussed by R. Amberg, G. F. McMahon, W. Sontag, and A. Müller. In C. F. Burgess and C. Hambüchen's process for the electrolytic purification of iron the electrolyte, at 30°, consists of a soln. of ferrous chloride mixed with ammonium chloride or sulphate ; the cathode current density is 0·7 to 1·1 amp. per sq. dm. The anode consists of wrought iron or steel. The current yield is 90 to 100 per cent. The process was discussed by G. F. McMahon, and B. Speed and G. W. Elmen. As an example, the anode of iron to be purified contained 0·06 per cent. C,. 0·05 P, 0·23 Si, 0·3 to 0·5 Mn, and 0·10 S ; whilst the cathodic deposit of electrolytic iron contained 0·014 per cent. C, 0·013 P, 0·028 Si, 0·029 Mn, and 0·003 S. Société de Fer Grenoble, A. Boucher, and A. Bouchayer developed a process for purifying pig-iron by using it as a rotating anode in a bath of ferrous chloride or sulphate, or a mixture of both. The process was examined by D. Belcher, J. Escard, L. Guillet, and B. Stoughton. H. Krämer, and H. Meidinger observed that with a soln. of ammonium chloride and ferrous sulphate as electrolyte the iron obtained contained both chloride and nitride.

According to A. T. C. Estelle, iron can be obtained by electrodeposition from a suspension of ferric oxide in a hot conc. soln. of sodium hydroxide. The process was examined by S. J. Lloyd, who found that the current efficiency is high, and the estimated power consumption is 3000 to 3300 kw.-hrs. per ton of iron. C. P. Perin and F. A. Eustis proposed to obtain electrolytic iron from sulphide ores by first grinding the ore to a pulp with spent electrolyte—a mixture of ferric and ferrous chlorides. There is a reaction : $2FeCl_3 + FeS = 3FeCl_2 + S$, which is nearly complete with pyrrhotite and about 60 per cent. completion with pyrite. Any copper which passes into soln. is precipitated by metallic iron. The soln. is then electrolyzed in a diaphragm cell with graphite anodes. Iron is deposited in the cathode compartment, and ferric chloride is formed in the anode compartment. The electrolyte is kept in circulation, and its concentration does not exceed 70 grms. per litre of $FeCl_3$, and about the same with $FeCl_2$. When conditions are right, iron is deposited at high current efficiency, exceeding 95 per cent. That is to say, 1 grm. of iron may be had per ampère-hour. The amount per kilowatt-hour depends, of course, on the resistance of the cell, which in turn depends upon the composition and temp. of the electrolyte, but more particularly on the current density. For instance, other conditions being equal, a current density of 20 ampères per sq. foot requires 1 volt, 40 ampères 2 volts, and 160 ampères 4 volts. Modifications of the process for titanium ores were made by R. H. Monk and R. J. Traill ; somewhat similar principles were applied by W. Pip, R. D. Pike and co-workers, R. J. Traill and W. R. McClelland, and A. J. Moxham. F. Förster, and O. Mustad obtained good results by additions of boric acid to the bath of ferric chloride ; E. F. Kern, S. A. Tucker and E. Schramm, J. R. Cain and co-workers, F. Fischer, Langbein-Pfanhauser Werke, C. Arzano and G. Clerici, F. Förster, H. Plauson and G. Tischtschenko, G. Vié, A. Nodon and A. Lecandre, W. C. McWilliams, H. Lee, Allgemeine Elektrizitäts-Gesellschaft, A. Pfaff, and G. F. McMahon used additions of sodium or ammonium chloride ; and F. Fischer, H. D. Hineline, W. E. Hughes, and Langbein-Pfanhausen Werke used additions of calcium or magnesium chloride. H. D. Hineline also recommended a bath of 200 grms. each of $FeCl_2$ and $CaCl_2$, 20 grms. of chromous chloride, and 5 grms. of hydroquinone per litre at 30°, with a current density of 2·7 to 8 amps. per sq. dm.

E. F. Kern obtained a deposit of brittle, dark grey iron contaminated with some silica by the electrolysis of a sat. soln. of iron in 31 per cent. hydrofluosilicic acid, using a current density of 1 to 2 amps. per sq. dm. and 0·9 to 1·2 volts at 20°, or 0·51 to 0·70 volt at 60°. E. F. K. Harbeck obtained good results with additions of alkali or alkaline earth sulphates, chlorides, or fluorides. H. Oettinger used a soln. containing some free hydrofluoric acid ; and H. Plauson and G. Tischtschenko, soln. of fluosilicates or fluoborosilicates. M. Schlötter electrolyzed soln. of ferrous perchlorate—say 100 grms. $FeCl_2$, 200 grms. $Fe(ClO_4)_2$, and 2 grms. perchloric acid

in a litre of water—and obtained a deposit with a very fine-grained crystalline structure. A. Brand electrolyzed an ammoniacal soln. of sodium ferrous or ferric pyrophosphate ; T. Moore, a soln. containing ferric sulphate, metaphosphoric acid, and ammonium carbonate ; G. Gore, and R. Böttinger, a soln. of potassium ferrocyanide ; and G. Gore, a soln. of potassium ferrate. The general subject was discussed by G. Fuseya and co-workers.

G. Vortmann used as electrolyte a soln. of a ferrous salt mixed with an alkali tartrate and hydroxide, and A. K. Balls and C. C. McDonnell used a similar soln. with the alkali hydroxide in considerable excess. A. T. C. Estelle found that iron can be obtained by the electrolysis of the slime obtained by the action of alkali hydroxide or carbonate on iron oxide at a high temp. Iron alloys were also obtained by using a mixture of oxides instead of iron oxide alone. F. K. Bezzenberger obtained iron by the electrolysis of a soln. of ferrous sulphate containing in suspension precipitated iron hydroxide. A. Simon electrolyzed soln. of ferric oxide in molten calcium fluoride, when phosphorus and silicon if present are liberated from the anode as fluorides. Carbon electrodes and a current density of 600 to 700 amps. per sq. dm. were employed.

R. H. Aiken electrolyzed molten ferrous silicate containing lime or magnesia and iron oxide in soln. The electrodeposition of iron from molten electrolytes was discussed by J. W. Beckman, G. Hofer, F. Sauerwald, and F. Sauerwald and G. Neuendorff. E. M. Chance employed an anode of fused sulphide, and with fused sodium metasilicate as electrolyte and a steel cathode. He found that copper, nickel, and iron could be separately deposited, in the order named, by raising the current density. Sulphur, arsenic, and antimony volatilized at the anode. R. H. Aiken found that when a molten sulphide is electrolyzed, copper and nickel, if present, are first deposited and iron sulphide remains. By increasing the current density iron is deposited. The subject was studied by T. D. Yensen, and R. D. Pike and co-workers.

W. Hampe, and A. H. W. Aten and co-workers obtained iron by the electrolysis of the fused chloride. F. Krupp proposed to refine cast iron by using it as anode in molten halides. S. Grünauer found that in the electrolysis of a mixture of fused zinc and ferric chlorides the iron deposited on the cathode before the zinc ; and H. J. Blikslager obtained a similar result with a fused mixture of ferrous and manganous chlorides at 470°. F. Andersen showed that the electrolysis of a mixture of ferrous chloride and a fused eutectic mixture of potassium and lithium chlorides gives iron of a high degree of purity.

Iron can be readily deposited from soln. where the iron is present as a complex salt of organic acids. Thus A. Neuburger, and K. Schild used an electrolyte of ferrous sulphate mixed with ammonium oxalate ; F. Exner, and W. Fischer, a soln. of ammonium ferric sulphate and ammonium oxalate ; and A. Classen and co-workers, G. Parodi and A. Mascazzini, A. Skrabal, S. Avery and B. Dales, W. Sontag, H. Verwer and F. Groll, and J. Früh, ferric or ferrous sulphate or chloride and ammonium oxalate. Platinum foil was often used as cathode and a platinum wire as anode, with a current density of 0·01 amp. per sq. cm. at 20°. Salts of other acids, carbonates, formates, acetates, succinates, tartrates, and citrates have also been tried by S. Avery and B. Dales, R. Ehrenfeld, P. K. Frölich, A. Skrabal, J. Früh, M. Heidenreich, G. Luckow, R. Kremann and co-workers, O. Orlandi, H. Schmidt, E. F. Smith, and H. Verwer. The addition of other organic substances has been tried. A. Ryss and A. Bogomolny observed no particular advantage to attend the addition of various alcohols, organic acids, esters, aldehydes, or ketones ; and O. P. Watts and N. H. Li, the addition of phenols, bases, sugar, and colloids, although formaldehyde and hexamethylenetetramine exerted a favourable influence. R. Kremann and co-workers tried additions of glycerol ; M. Schlötter, glycol, chlorhydrin, and dichlorhydrin ; E. H. Archibald and L. A. Pignet, soln. of ferric chloride in acetone, ethyl alcohol, and mixtures of acetone with water or alcohol. W. A. Macfadyen obtained poor results with glue, gelatin, and β-naphthol ; and

S. O. Cowper-Coles, creosol and sulphuric acid. S. O. Cowper-Coles' process was examined by E. H. Archibald and L. A. Pignet, D. Belcher, W. Heyn, and B. Neumann.

The contamination of iron with carbon when the metal is deposited from electrolytes containing organic acids has been observed. E. F. Smith and F. Muhr said that tartrates give a variable proportion of carbon; G. Parodi and A. Mascazzini, that oxalate soln. gave a deposit with 0·5 per cent. of carbon— S. Avery and B. Dales, 0·21 to 0·42 per cent.; E. F. Smith, that citrate soln. gave a deposit with 0·5 per cent. These results are high, and much smaller proportions were observed by H. Verwer and F. Groll. The subject was also discussed by E. H. Archibald and L. A. Pignet, L. Balbiano and A. Alessi, F. Förster, P. K. Frölich, A. Glazunoff and A. Rozmus, A. Müller, G. Lambris, C. P. Madsen, H. Schmidt, A. Skrabal, W. Sontag, J. Tafel and G. Friedrichs, and H. Verwer. With electrolytic iron obtained by other processes J. Billiter reported 0·06 per cent. of carbon; A. Bouchayer, 0·029; C. F. Burgess and C. Hambuechen, 0·013; O. W. Storey, 0·012; T. D. Yensen, 0·010; J. Escard, 0·008; G. P. Fuller, 0·006; N. B. Pilling, 0·005; A. Vosmaer, 0·004; and E. Duhme, 0·002. W. C. Roberts-Austen prepared electrolytic iron from a soln. of ferrous and magnesium sulphates of so high a degree of purity that the metal contained only 0·007 per cent. of carbon and 0·005 per cent. of sulphur. K. Oma found that iron deposited from ammonium ferrous sulphate baths may contain 0·001 per cent. of sulphur as sulphide derived from the anode material, and 0·02 to 0·03 per cent. as sulphate derived from the electrolyte. At high temp. the sulphate may be reduced to sulphide and then to hydrogen sulphide. The rate of desulphurization by hydrogen above 800° is a function of time, temp., and grain-size.

Iron has also been deposited from soln. of its salts in non-aqueous solvents by electrolysis between platinum electrodes. Thus J. Timmermans used a soln. of ferric chloride in methyl chloride; H. E. Patten and W. R. Mott, a soln. of ferric chloride in acetone at ordinary temp. and with a large current density; and E. H. Archibald and L. A. Pignet, a soln. of ferric chloride in acetone, ethyl alcohol, and mixtures of the two. The iron is free from carbon when deposited from the acetone soln. At low voltages the iron is in the metallic state, but at higher voltages the deposit is red. The iron deposited from the acetone-alcohol soln. is contaminated with carbon. H. Röhler obtained no electrodeposit from soln. of iron salts in formamide; L. F. Audrieth and L. F. Yntema, and H. S. Booth and M. Merlub-Sobel obtained a similar result with soln. in liquid ammonia. H. E. Williams electrolyzed a soln. of ferric chloride in ether, and found that with high current densities and conc. soln. iron is deposited, but with dil. soln. and low current densities ferrous chloride is formed. R. Müller and co-workers found that a soln. of ferrous bromide in pyridine at ordinary temp. furnishes deposits of grey, passive iron. G. Fuseya and co-workers examined the effect of glycerol on the electrolyte to find if it enters the electrodeposit and influences the grain-size.

Analyses of electrolytic iron have been reported by J. Billiter, A. Bouchayer, C. F. Burgess and C. Hambüchen, E. Duhme, J. Escard, G. P. Fuller, L. Guillet, N. B. Pilling, O. W. Storey, and T. D. Yensen. The proportion of iron ranges from 99·963 to 99·971 per cent. The proportion of carbon—*vide supra*—ranges from 0·002 to 0·060 per cent.; and that of sulphur—*vide supra*—from mere traces to 0·016 per cent. The proportion of phosphorus ranges from 0·0001 to 0·041 per cent., and observations on the subject were also made by S. Avery and B. Dales, E. Duhme, L. Guillet and A. Portevin, and T. Moore. The silicon content ranges from 0·001 to 0·11 per cent. The manganese content was discussed by A. Pfaff; the copper, by G. P. Fuller; the lead, by G. Tammann; 0·004 per cent. of arsenic was reported by J. Billiter; and the oxygen or oxide content, by E. F. K. Harbeck, E. F. Kern, and A. Skrabal; for the chloride content, *vide supra*; and for the proportion of occluded gases, *vide infra*, the chemical properties of iron.

T. D. Yensen recommended fusing electrodeposited iron in vacuo in order to

reduce the proportion of impurities, and he found that the metal so obtained had a permeability two or three times greater than that previously obtained for the iron of the highest degree of purity. G. K. Burgess, E. Duhme, and O. W. Storey discussed the preparation of iron of a higher degree of purity.

Electrolytic iron is not homogeneous, since it contains gas pores, occluded gases, and foreign inclusions, and L. Schäfer emphasized the fact that it is liable to have a lamellar structure. A. Skrabal's observations on two forms of electrolytic iron are discussed below. V. Kohlschütter said that the crystalline character of electro-deposited iron is determined by the mode of arrangement of the individual crystals to form the aggregate, as well as the form, habit, and size of the individual crystals. As in other crystallization processes, growth of existing crystals and formation of new nuclei are differently affected by changing conditions, and wide variations in the character of such deposits are possible. C. Marie and N. Thon discussed the subject.

Numerous factors may operate in determining the character of the cathodic deposit, for the growth of the deposit is affected not only by the forces of crystalliza-tion but also probably by the forces in soln. A. K. Graham, G. Eger, R. Glocker and E. Kaupp, R. H. Greaves, and R. Audubert discussed the structure of electro-lytic iron, and of the factors concerned in the production of symmetrical, columnar, fibrous, and powdery deposits. For V. Kohlschütter and E. Vuilleumier's observa-tions on the formation of a colloidal, highly dispersed layer on the cathode in the first stages of the electrolysis, *vide* nickel. According to W. Blum and H. S. Rawdon, the cathodic discharge of metal-ions and the formation of crystals constitute one and the same process, and any given ion is discharged at the point at which the lowest discharge potential is required. The discharge potential is a function of the soln. press. of the metal and the " effective " metal-ion concentration adjacent to it. The single potential and solution pressure of a metal are the resultant of the " primary single potential," which is defined in terms of the solution pressure of a single unorientated atom, and the " orientation potential," which is a measure of the diminution in solution pressure and corresponding algebraic increase in single metal potential caused by the orientation of the adjacent metal atoms. A higher potential is required to discharge an ion in a position unrelated to those of previously discharged atoms than on an existing crystal, and similarly a higher potential is required to discharge an ion on a small crystal than on a large one. There are three main types of structure : (i) those in which all, or practically all, the initial nuclei continue to grow ; (ii) those in which only part of the initial nuclei continues to grow ; and (iii) those in which none of the initial nuclei continue to grow.

According to V. Kohlschütter and F. Jakober, the superposition of an alternating current on the direct current during the electrolysis tends to make the crystalline structure coarse-grained. The orientation of the crystals was discussed by R. Audubert, A. Müller, R. M. Bozorth, F. Förster, W. E. Hughes, W. A. Macfadyen, L. B. Hunt, and O. W. Storey. According to O. W. Storey, electrolytic iron changes to the usual fine-grained structure at the A_3-arrest, and no change was observed when this form of iron was heated at a lower temp. The manufacture of electrolytic iron has been described by F. Sauerwald and G. Neuendorff, S. J. Lloyd, C. Hambüchen, G. P. Fuller, T. Johnston, F. A. Eustis and C. P. Perrin, A. Bouchayer, E. C. Kreutzberg, T. W. S. Huchins, F. N. Budgen, D. Belcher, R. H. Monk and R. J. Traill, W. A. Noyes, W. E. Hughes, A. Levasseur, D. R. Kellogg, G. F. McMahon, N. B. Pilling, R. P. Neville and J. R. Cain, B. Stoughton, H. D. Hineline, M. L. V. Gayler, and R. Dupuis.

In some of the old bloomery processes for extracting iron from its ores, the metal was obtained as a more or less spongy mass. The product furnished by A. Chenot's [4] process is in the form of **spongy iron**—*éponge métallique*. Spongy iron was extracted in Sweden, before the 1914–18 war, and exported for use in the open-hearth process. Alternate layers of iron ore and coal were heated by producer gas at a temp. between 1050° and 1200°. According to J. O. Handy, the spongy iron has 96 to 97 per cent. Fe ; 0·01 to 0·02, S ; 0·012, P ; and 1·4, Si. E. P. Barrett described the production

of spongy iron and the absorption of sulphur by that form of metal. The subject was discussed by B. Stoughton, E. P. Barrett, F. Wüst, W. Rohland, A. Adams, G. Mars, J. von Ehrenwerth, S. E. Sieurin, E. de Billy, C. E. Williams and co-workers, C. A. Keller, A. E. Bourcoud, F. Krupp, M. Wiberg, W. W. Percy, J. Y. Johnson, N. K. G. Tholand, B. Britton, and P. Longmuir—*vide supra*. P. Longmuir found the iron contents varied from 90 to 97 per cent., and, in addition, contained 4 per cent. of oxygen ; 1·3, C ; 5·2, Si and slag ; 0·2, P, Mn, etc. As shown by F. Hatton, spongy iron can be used as a reducing agent in organic chemistry. By its aid combined nitrogen is reduced to free nitrogen, and in some cases methane is produced.

G. Magnus [5] obtained powdered and **pyrophoric iron** by reducing many compounds of iron in a current of hydrogen at a relatively low temp.—between 360° and 420°. L. Troost and P. Hautefeuille also obtained it from ferric oxide : F. Wöhler, M. Zängerle, F. Göbel, A. Vogel, S. Birnie, and G. S. Newth also obtained it by reducing the oxide, carbonate, or oxalate with hydrogen or carbon dioxide. F. Wüst and P. Rütten observed that the minette ore gives pyrophoric iron when reduced in hydrogen. H. Moissan obtained it by heating the oxalate at about 440° ; A. Smits and co-workers, from ferrous tartrate, citrate, chloride, or oxide at about 350° ; T. G. Finzel, from hydrated ferric oxide free from chlorides ; C. J. Sims and E. W. J. Mardles, and A. Mittasch and co-workers, by the decomposition of iron pentacarbonyl ; and A. Job and R. Reich, by the action of ethyl magnesium bromide on ferrous iodide. H. Moissan observed that the reduction of ferric oxide is very slow at 435°, and 96 hrs. were needed to obtain iron free from ferrous oxide ; the reduction proceeds rapidly at 600°, but the product is not pyrophoric. G. Magnus observed that pyrophoric iron prepared from a mixture of ferric oxide and alumina retains its pyrophoric quality after heating to redness, but S. Birnie found that when prepared from the oxalate it loses its pyrophoric quality at 470°, but not when heated in nitrogen or hydrogen at 430° to 440°. G. Tammann and N. Nikitin observed that iron obtained by reducing the oxide in hydrogen at 370° to 530° is pyrophoric, but above 530° it is not pyrophoric ; and A. Smits and G. Wallach were able to obtain pyrophoric iron by reducing the oxide at 600°, and found that its activity decreased steadily as the temp. was raised to 710°, beyond which the iron was no longer pyrophoric. The reduction occupied an hour and a half, and thoroughly dried hydrogen was employed. The best temp. was found to be 450°, when the reduction occupied 5 hrs. M. Siewert stated that the iron loses its pyrophoric qualities if kept in hydrogen for 12 hrs., but this has not been confirmed ; A. Smits and co-workers found that the pyrophoric quality is lost when the iron is heated in a high vacuum at 300°, and there is a marked decrease in the pyrophoric quality when heated to 650° in purified dry hydrogen. F. Wüst and P. Rütten found that the pyrophoric iron from minette ore loses its pyrophoric quality if heated in hydrogen at 700° ; and K. Hofmann found that natural ferric oxide is pyrophoric when reduced below 600° for less than 45 mins., but if heated for a longer time the reduced iron is no longer pyrophoric. T. G. Finzel observed that the pyrophoric quality is retained in dry air at −78°.

The general idea is that the temp. of the reduction employed in the preparation of pyrophoric iron is so low that a skeleton framework of iron atoms remains where the iron oxide molecule was present, and that the thermal movement of the atoms of iron at the low temp. is too sluggish to allow of their orientation into the dense and more compact crystalline state which is the stable form at that temp. In consequence, pyrophoric iron is wholly or partly in the colloidal state, pseudomorphous after iron oxide. G. Magnus attributed the pyrophoric quality to the extremely finely-divided state of the product of the low-temperature reduction, and if the reduction occurs at a higher temp., the product is coarser grained. The absorption of oxygen by the fine-grained powder is enough to raise the temp. to the ignition point. The oxidation of occluded hydrogen by the metal was also thought by G. Magnus, and L. Troost and P. Hautefeuille to have some influence on the

result. S. Birnie added that the presence of finely-divided carbon has no positive influence on the pyrophoric quality. F. Stromeyer, and J. W. Gilles considered that the presence of lower oxides which have escaped reduction favours the pyrophoric quality. B. Osann, K. Hofmann, F. Sauerwald and G. Elsner, and G. Tammann and co-workers agree that the pyrophoric quality depends on the extent of the free surface exposed by the powder to air ; but A. Smits and co-workers could detect no difference in the sizes of the particles of pyrophoric and non-pyrophoric iron, and they conclude that the pyrophoric quality is due to the metal being in a metastable state. W. Frankenburger and K. Mayrhofer heated a spiral of iron in an atm. of nitrogen at 0·1 to 0·01 mm. press., while the vessel was cooled in liquid nitrogen. They thus obtained finely divided or " atomized " iron.

In 1787, M. van Marum [6] obtained deposits of thin films, the so-called **iron mirrors,** of iron on glass by passing an oscillating electric discharge through a thin iron wire. M. Faraday also obtained thin films by cathodic spluttering in hydrogen. K. Lauch and W. Ruppert obtained a film on a polished crystal of rock salt by means of cathodic spluttering, and then removed the salt with water. This furnished a thin, elastic film of the metal. A. W. Wright emphasized the importance of preparing the films in an atmosphere free from oxygen and moisture. The results are good when the spluttering occurs either in vacuo or in an atmosphere of hydrogen gas ; B. Dessau said that an atm. of hydrogen at 1 mm. press. gives good results. Observations were also made by F. Braun, H. Freundlich and co-workers, J. de Kowalsky, A. Kundt, L. R. Ingersoll, J. Moser, A. Skinner and A. Q. Tool, J. Strong and C. H. Cartwright, W. W. Nicholas, A. Ungerer, G. P. Thomson, J. Y. Johnson, and S. Procopiu. J. Y. Johnson, and H. Freundlich and co-workers obtained a mirror by the thermal decomposition of iron pentacarbonyl in an evacuated glass vessel. According to R. Brill, the grain-size of iron liberated by the thermal decomposition of iron carbonyl is 10^{-6} cm. W. Frankenburger and K. Mayrhofer, and G. W. C. Kaye and D. Ewen obtained a mirror which was not homogeneous by the sublimation of iron in vacuo ; A. Knocke also obtained a mirror by heating iron powder in an evacuated tube at 755° ; F. H. Constable, by heating a paste made of ferrous oxalate or ferric oxide in oleic acid ; E. Tiede and E. Birn-bräuer, by heating iron in vacuo ; and the Maschinebauanstalt Humboldt, by direct heating, or by an electric arc formed with one of the electrodes of iron. G. Belloc, J. H. Howey, L. Houllevigue, P. Lambert and A. Andant, A. J. Sorensen, and J. C. Steinberg also prepared iron mirrors in analogous ways. A. Kundt prepared a mirror by electrolysis, and likewise also E. Breuning and O. Schneider, and C. Müller. Ž. Debinska found thin metallic films obtained by vacuum distillation exhibit orientation of the micro-crystals. G. F. Taylor made **thin filaments** by drawing out the molten metal enclosed in a suitable glass tube and removing the glass with hydrofluoric acid.

The **aerosols** of iron were described by J. Fischer.[7] According to H. Freundlich, and T. Svedberg, the disperse phase obtained by spluttering iron under water, **colloidal iron,** contains more or less hydrated ferric oxide. This form of iron was produced by F. Ehrenhaft by G. Bredig's method—**3.** 23, 10—using an arc from iron wire electrodes under water. G. Bredig did not have much success with this process, but a similar one was successfully used by E. F. Burton, P. N. Pavloff, T. Malarsky, O. Scarpa, and D. Zavrieff. J. Billiter used zinc wires on which a film of iron had been deposited electrolytically. T. Svedberg obtained a colloidal soln. of iron in ether by allowing sparks to pass between iron wire chippings immersed in that liquid and connected with an induction coil. R. Gans studied the optical properties and the absorption spectrum of the colloidal soln. and as a result inferred that the particles are not disc-shaped.

The **hydrosol** of iron is not very stable, and A. Schmauss found this defect mollified by the use of gelatine as protective colloid. The colloid can also be obtained by chemical methods ; thus, E. Richter obtained the hydrosol by treating a 2·5 per cent. soln. of ferric sulphate with 1 to 3 drops of a soln. of dimethylpara-

phenylenediamine (1 : 4000) ; H. Crookes and L. Stroud, by treating a mixture of a 1 per cent. soln. of ferrous chloride, free from alkali, and a neutral soln. of peptone containing 9·5 grms. per litre, with a small quantity of phenol ; and H. H. Franck, by reducing a dil. soln. of an iron salt in the presence of a protective colloid—like gum arabic, gelatin, gum tragancath, and saponin. B. C. Soyenkoff made sols of iron soaps in benzene. According to C. Serono, when a soln. of gelatin and a dil. soln. of an alkali chloride or sulphate is electrolyzed between iron electrodes, a colloidal soln. of iron is obtained mixed with some colloidal ferrous hydroxide and a ferric salt. The metal is positively charged. The Chemische Fabrik von Heyden also prepared the colloid by electrical spluttering under a soln. containing a reducing agent and a protective colloid—for instance, 0·75 grm. of pyrocatechol and 1 grm. of albumose or albumen in a litre of water. P. von Mutzenbecher used paraglobulin as protective colloid.

M. Traube-Mengarini and A. Scala thought that some colloidal iron is spontaneously formed by cold or boiling water in contact with iron, but H. Nordenson showed that this is not the case. What actually occurs is the formation of colloidal hydroxide when air has access to iron. E. F. Burton and P. Phillips' observations on the magnetic susceptibility of colloidal soln. of iron agree with the assumption that the particles of iron are surrounded by a film of hydroxide. F. Fischer and F. Schröter observed no colloid is formed in the direct current arc with iron electrodes under liquid argon.

G. Bredig did not obtain a stable **ethersol** by forming a direct current arc under ether, and G. Bredig's process was found by T. Svedberg not to be applicable to the formation of organosols of iron, because of the decomposition of the organic medium, but he did obtain an ethersol by the oscillating discharge—**3.** 23, 10— between iron electrodes under ether in the presence of the finely-divided metal. T. Svedberg also prepared **alcoholsols** with propyl and *iso*butyl alcohol, and **acetono- sol** with acetone. H. B. Weiser and G. L. Mack obtained alcoholsols, etc. ; E. Berl and co-workers, various organosols using rubber as a protective colloid when the dispersion medium is a hydrocarbon ; F. Haurowitz obtained **benzene- sols** ; and E. F. Burton, a sol with methyl alcohol. H. Nordenson obtained no alcoholsol by boiling ethyl alcohol in the presence of iron, nor by exposing an iron plate in contact with methyl or ethyl alcohol to X-rays or to ultra-violet rays. F. Haurowitz prepared by T. Svedberg's method benzenesol with benzene as dispersion medium and non-vulcanized caoutchouc as protective colloid. C. J. Sims and E. W. J. Mardles obtained a petroleum sol from a soln. of iron pentacarbonyl in petroleum, **naphthalene sol** from a soln. of the same substance in naphthalene, and **bromonaphthalene sol** by using bromonaphthalene as solvent. A. Cotton and H. Mouton obtained a **glycerol sol** by arcing iron under glycerol; some of the medium is decomposed   C. Benedicks observed that when the conditions are such that arc discharge takes place for a very short interval of time, as may easily be arranged if the current is furnished by an induction coil and a Leyden jar placed in parallel with the discharge gap, the surfaces of the electrodes exhibit well-formed eruptive craters, which are attributed to the melting of the metal under the influence of the discharge. When the discharge ceases, the surrounding liquid comes in contact with the hot metal, and this is supposed to be directly responsible for the disintegration of the electrodes. Ultra-microscopic observations show that the particles are spherical and have a diameter varying over a wide range, with an upper limit of about 5μ. D. C. Bahl studied the flocculation of the sol.

§ 12. The Allotropes of Iron

L'utile bien considéré a toujours du curieux et il est rare que le curieux bien suivi ne mène pas à l'utile.—R. A. F. DE RÉAUMUR.

The first recorded observation on the discontinuity in the properties of iron and steel was made at the beginning of the seventeenth century by W. Gilbert,[1] in his *De magnete* (London, 1600). He found that when a magnet is heated to redness, it loses all traces of magnetization. About half a century later, T. Brown, in his *Pseudodoxia epidemica* (London, 1650), also said that the magnetization of iron is affected by temp., for he observed that " by the fire, iron abandons whatsoever it has received from the loadstone." In developing his *théorie de la trempe*, C. E. Jullien seems to have had a notion that iron can exist in allotropic forms. About 1820, J. Cumming noted that the thermoelectric current between iron and other metals is reversed at a red-heat. In 1869, G. Gore pointed out that when a bar of iron is heated to redness, a whole series of changes occurs in its molecular structure, as shown by observations on its magnetism, its dimensions, its cohesive power, its sp. ht., its thermoelectric capacity, and its electrical conductivity. Thus, on cooling a red-hot iron wire a sudden dilation occurs while the iron is still at a red-heat, and at this temp. the iron suddenly becomes magnetic. In 1873, W. F. Barrett observed that if a piece of steel be heated to redness and allowed to cool, it progressively becomes darker and darker until a certain temp. is attained, when there is a sudden evolution of heat, which is sufficient to raise the temp. of the mass and render it perceptibly brighter. The phenomenon is called *recalescence*. The facts were confirmed by the observations of M. Aliamet, C. Barus, C. Bauer, C. Benedicks, F. G. A. Berson, J. H. Brinell, W. Broniewsky, H. L. Callendar, H. le Chatelier, G. Chrystal, J. Coffin, G. Forbes, G. Heim, E. Heyn, J. Hopkinson, H. Hort, H. M. Howe, A. Ledebur, C. G. Knott, W. Kohlrausch, P. H. Ledeboer, H. F. Newall, R. Norris, R. C. Gale, A. Nouel, J. E. N. Pionchon, H. W. B. Roozeboom, E. Saladin, H. Scott, C. M. Smith and co-workers, A. Stadler, P. G. Tait, A. Schulze, and H. Tomlinson. A. Mallock noted that as the proportion of carbon in the iron is increased the temp. at which recalescence occurs is lowered—*vide infra*. W. Metcalf, and J. O. Arnold raised the question whether or not the recalescence in steel is due to a change from the plastic to the crystalline state ; and the subject was discussed by F. Osmond, and J. O. Arnold. The hypothesis was sterile.

In 1887, F. Osmond showed that if an iron bar be cooled from its m.p. to 0°, the time-temperature cooling curve shows three breaks or arrests. The arrests are due to the evolution of a small amount of heat, whereby the rate of cooling is

retarded. The evolution of heat is produced by some internal change in the metal; these changes are reversible, because the heating curve of iron shows three breaks. The arrests on the heating curve occur at a slightly higher temp. than those on the cooling curve. The difference in the temp. obtained by the heating and cooling curves is due to a certain amount of hysteresis, lag, inertia, or resistance to change; the resulting lag tends to lower the temp. of the arrest during the cooling, and to raise it during the heating. D. K. Tschernoff, and F. Osmond represented the discontinuities by the symbol A, from the initial letter of the French word *arrestation*, or arrest, and the arrests on the cooling curve were symbolized Ar, where r is the initial letter of the word *refroidissement*, cooling; and those on the heating curve were represented by Ac, where c is the initial letter of the French word *chauffage*, heating. The approximate temp. at which the breaks occur in the cooling and heating curves are:

Heating	.	.	.	Ac_4, 1404°	Ac_3, 910°	Ac_2, 770°
Cooling	.	.	.	Ar_4, 1400°	Ar_3, 890°	Ar_2, 760°
Average	.	.	.	A_4, 1400°	A_3, 906°	A_2, 768°

J. O. Arnold, W. Reinders and P. van Groningen, and E. Colver-Glauert showed that with the iron of a very high degree of purity the Ar_2-arrest may show as a double or twinned arrest. The subject was discussed by J. Driesen, A. E. Oxley, P. N. Laschtschenko, A. I. Brodsky, M. Oknoff, and M. Temnikoff. Breaks also occur in the curves relating the temp. with other physical properties— sp. gr., tensile strength, sp. ht., electrical resistance, magnetic susceptibility, thermo-electric force, etc. There are several possible explanations of these **critical temperatures.** F. Osmond suggested that they represent changes from one allotropic form to another. This means that there are four **allotropic states** of iron. The form stable at ordinary temp. and up to about 769°—*i.e.* A_2—is called α-**ferrite,** or α-**iron**; that form stable between 769° and 906° is called β-**ferrite,** or β-**iron**; and that between 906° and 1404°, γ-**ferrite,** or γ-**iron.** Owing to hysteresis or lag these arrests are not necessarily sharply defined, but represent regions or zones within which the assumed allotropic changes occur. K. Honda and S. Miura, and G. K. Burgess and co-workers, for example, found that with a cooling or heating rate of 2° per minute the A_3-arrest for purified iron begins at 860° and ends at 850°. These intervals may be widened if other elements be present—*e.g.* nickel (*vide infra*). The ranges of stability of the four phases are: α-iron up to 768°; β-iron between 768° and 906°; γ-iron between 906° and 1400°; and δ-iron between 1400° and the m.p. If with L. Cammen, C. H. Desch, W. Guertler, K. Honda, R. Ruer, F. Sauerwald, G. Tammann, F. Wever, and others, the β-phase be considered as a non-magnetic form of the α-phase, and the definition of an allotropic phase be phrased to exclude the inclusion of non-magnetic forms as true allotropes, the ranges of stability of the three phases will be: α-iron up to 906°; γ-iron between 906° and 1400°; and δ-iron between 1400° and the m.p. F. Wever, H. Hanemann and A. Schrader, and P. Oberhoffer observed that the polished and etched surfaces of α- and β-ferrite appear as irregular grains; and γ-iron shows twinned crystals. A. Perrier and F. Wolfers reported a break in the heating curve at 1130°.

E. J. Ball first observed the A_4-arrest at about 1300° with iron containing 0·12 per cent. carbon; and this probably represents the transformation of δ- into γ-ferrite, subsequently observed by R. Ruer and F. Goerens, when allowance is made for the lowering of the transition temp. by carbon. With purified iron R. Ruer and F. Goerens observed that the temp. between 1404° and the m.p., 1505°, represents the zone of stability of δ-**ferrite,** or δ-**iron.** These temp. were given by R. Ruer and F. Goerens as the best representative values. The idea is illustrated diagrammatically in Fig. 76. At the critical temp. two forms are in equilibrium with one another.

The X-radiograms of the different forms of iron (*vide infra*) show that the

crystals of δ-ferrite have a body-centred cubic lattice ; those of γ-ferrite have a face-centred cubic lattice ; whilst those of β- and α-ferrite have an identical body-centred cubic lattice. The change from β- to α-ferrite at about 770° is not connected with any change in crystal form, but it happens that at this temp. the magnetic permeability of the iron increases very rapidly, and the arrest is accordingly sometimes termed the temp. of *magnetic transformation.* Thus, R. Ruer and K. Kaneko regarded the change as a transformation of a non-magnetic crystalline form into a ferromagnetic one.

FIG. 76.—Differential Cooling Curve of Iron (Diagrammatic).

A. Smits distinguishes between what he calls heterogeneous and homogeneous allotropy, and believes that in the case of heterogeneous liquids or solids two different forms or phases co-exist in equilibrium. The relative proportions of the two forms vary with temperature. At the so-called transition point there is a sudden disturbance in the conditions of equilibrium. Otherwise expressed, the equilibrium condition is a discontinuous function of temp. This is supported by the fact that the f.p. of sulphur, phosphorus, tin, etc., vary with the temp. at which equilibrium has been attained. Mercury is homogeneous and the f.p. is independent of its previous thermal treatment. The transformation corresponding with the change in some property may be abrupt, as in I, Fig. 77. Again, one—II or III, Fig. 77—or both—IV or V, Fig. 77—modifications may be soluble in the other and the curve may show all degrees of continuity, and there will then be a range of temp. within which the transformation takes place—V, Fig. 77. The allotropic transformation then involves the splitting up of a homogeneous solid soln. of two modifications or phases. The subject was discussed by C. Benedicks, H. M. Howe, H. C. H. Carpenter, A. Holt, E. Cohen and G. de Bruin, and A. Smits. According to K. Honda and H. Takagi, the β→α transformation extends over a small interval of temp., and the interval with both the β→α and the γ→α transformations increases as the proportion of carbon contained in steels is augmented—*cf.* Fig. 76.

The A₂-point.—Although A. Kroll, and W. Rosenhain and J. C. W. Humfrey reported a difference in the *microstructure* of α- and β-phases, they could not satisfy themselves that there is a real difference ; nor could E. H. Saniter,
FIG. 77.—Abrupt and Graded Transformation Points.

J. E. Stead and H. C. H. Carpenter, and O. W. Storey detect any difference. The observations of F. Wever on the X-radiograms of the metal in the α- and β-states revealed no difference in the *space-lattices*, although R. Bach reported a discontinuity in the lattice constant between 750° and 860°. Observations by G. Charpy, and W. Rosenhain and J. C. W. Humfrey indicated an increase in the *hardness* as the metal passed through the A₂-arrest.

W. Rosenhain and J. C. W. Humfrey heated one end of a rod of purified iron in vacuo and simultaneously subjected the rod to strain. Three zones appeared : in the α-range the iron became weaker and softer as the temp. was raised ; in the β-range the iron was harder and stronger ; whilst in the γ-range the material developed a sharply defined crystalline structure and its strength was reduced. A. Sauveur heated bars of iron in the

middle whilst the ends were cold.   Pure irons always broke in the central hottest portion when they were twisted ; but if the centre of the bar was above the A_3-arrest, the greatest twist occurred at two points along the rods corresponding with the A_3-arrest.   This shows that iron is more plastic whilst passing through the A_3-transformation.   Again, F. Wever and P. Giani heated one end of a thin strip of iron in vacuo and observed that coarse crystals of δ-iron appeared where the temp. was over 1400° ; below that temp. finer crystals of γ-iron appeared ; and below 906°, α-iron formed crystals larger than γ-iron, but rather smaller than δ-iron.

The *heating and cooling* curves of purified iron by G. K. Burgess and co-workers, J. F. T. Berliner, and F. Wever gave 763° for the A_2-arrest ; R. Ruer and co-workers found 769° ; F. C. Thompson, Ac_2=765° ; P. Bardenhauer gave Ac_2=773° and Ar_2=771° ; W. C. Roberts-Austen, Ar_2=766° ; W. Gontermann, and G. Charpy and L. Grenet, A_2=770° ; A. Müller, and W. Rosenhain and J. C. W. Humfrey, Ac_2=770° and Ar_2=763°.   Observations were also made by J. O. Arnold, G. Belloc, W. Broniewsky, H. C. H. Carpenter and B. F. E. Keeling, P. Oberhoffer, A. Perrier and F. Wolfers, and A. Sanfourche.   According to G. K. Burgess and J. J. Crowe, and E. Maurer, the A_2-arrest does not show hysteresis phenomena ; the Ar_2-arrest, for instance, remains at 770° whether the rate of cooling is at the rate of 15 or 250 degrees per minute.   G. Tammann also found that the A_2-arrest is not affected by pressures up to 12,000 kgrms. per sq. cm.—*cf.* Fig. 92.   H. C. H. Carpenter found that the A_2-arrest is almost obliterated when electrolytic iron is repeatedly heated in vacuo so as to remove the occluded hydrogen. L. Guillet and A. M. Portevin observed that the presence or absence of adsorbed hydrogen had no particular influence on the A_2-arrest ; and A. Sauveur found that the position of the A_2-arrest is influenced by the previous thermal history of the metal ; thus, on a first heating to 1000° the Ac_2-arrest occurred at 725° ; on the eighth heating, at 769° ; on the ninth heating, at 781° ; on the tenth heating, at 783° ; and on the eleventh heating, at 783°.   This shows that by previous heatings and coolings there is a gradual drift of the A_2-point towards a constant value.   K. Honda observed that whilst the A_2-arrest represents a gradual change in which the equilibrium .condition is a continuous function of the temp., the A_3- and A_4-arrests take place at definite temp.   G. Sirovich supposed that there are two forms of α-iron, namely $α_1$-ferrite, stable at ordinary temp., and $α_2$-ferrite, stable above 370°.   He suggested that the former is hard and magnetic, and forms solid soln. with cementite ; whilst the latter is soft and magnetic, and not capable of holding carbon in solid soln.   The *specific heat* by P. Weiss and P. N. Beck gave for the at. ht., C_p, a peak at 753° when C_p=17·64 ; F. Wüst and co-workers, 755° when C_p=21·00 ; P. Weiss and co-workers, 784° when C_p=17·03 to 17·26 ; P. Oberhoffer and W. Grosse, 785° when C_p=27·90 ; S. Umino, 825° when C_p=14·53 for steel, and 820° when C_p=19·00 for armco iron ; H. Lecher observed a singular point in the sp. ht. curve at 740° ; P. N. Laschtschenko, one at 730° ; A. Meuthen, one at 780° ; W. Winkler, between 780° and 840° ; R. Durrer, between 725° and 780° ; and P. Oberhoffer, between 750° and 760°.   Observations were also made by J. Maydel—*vide infra*. C. Benedicks observed a very slight deflection in the *thermal expansion* curves at 760° to 775°, and another small deflection at 830°.   These very mild singularities are thought to be connected with magnetostriction.   Observations were also made by G. Charpy and L. Grenet, H. le Chatelier, P. Chevenard, J. Driesen, H. Esser, and E. Maurer.   The *electrical resistance* curves of G. K. Burgess and I. N. Kellberg showed a decided cusp at 757° ; and those of K. Honda and Y. Ogura, one at 798°.   Similarly, I. Iitaka gave A_2=790 ; A. Somerville, 785° ; W. Broniewsky, 750° to 850° ; A. R. Meyer, 700° ; P. Fournel, and O. Boudouard, 775°.   These singularities are supposed by F. Osmond to be connected with the A_2-arrest.   The subject was studied by P. Saldau.   The *thermoelectric force* curves by W. Broniewsky found a discontinuity at about 795° ; G. K. Burgess and H. Scott, and J. F. T. Berliner, one at 768°.   Observations on the subject were also made by C. Benedicks, and W. Geiss and J. A. M. van Liempt.   The *magnetic susceptibility* curve was found by H. le Chatelier, P. Curie, P. G. Tait, A. Regner, R. B. Fehr,

and P. H. Ledeboer to show singularities near the A_2-arrest corresponding with the temp. of magnetic transformation. In this way J. Hopkinson, E. M. Terry, and T. D. Yensen found the Ar_2-arrest is near 785° ; D. K. Morris, R. L. Wills, and K. Honda and H. Takagi gave $Ar_2=770°$ and $Ac_2=870°$; P. Curie, $Ac_2=745°$ and $Ar_2=741°$; P. Weiss and P. N. Beck, 753° ; P. Weiss, 756° ; K. Honda and Y. Ogura, 796° ; S. Sato, $Ac_2=790°$ and $Ar_2=786°$; and T. Ishiwara, 780° to 800° with purified iron, and this was lowered to 790° with low-carbon steels, and to 780° with high-carbon steels. K. Honda's observations are discussed in connection with the magnetic properties of iron ; he gave 790° for the Curie point of purified iron, and for carbon alloys, 770° ; and he regarded 770° as the Curie point of austenite, which he proposed designating the A_2'-point to show its relationship with the A_2-point of iron. P. Weiss and G. Foëx thought that their curves indicated the existence of two forms of β-iron, which they called respectively β_1-iron and β_2-iron ; but E. M. Terry showed that the supposed breaks were illusionary. P. Curie found that for stronger fields there is a tendency for the inversion to extend over a wider range of temp. ; K. Honda observed that variations in the field strength had no effect on the inversion, but K. Renger found a difference with different field strengths. The magnetic inversion—*vide infra*—was discussed by P. Dejean, G. Eger, S. Hilpert, K. Honda and co-workers, A. Perrier and F. Wolfers, G. Rümelin and R. Maire, R. Ruer and co-workers, F. C. Thompson, and P. Weiss and co-workers. A. B. Bagdasarian observed a break in the *equilibrium constant* of the reaction $FeCl_2+H_2 \rightleftharpoons 2HCl+Fe$ at different temp.

The effect of alloying elements on the A_2-arrest has not been closely investigated. It is lowered from 780° to 690° by 21 per cent. of titanium ; and it is also known to be lowered by carbon, nitrogen, chromium, and nickel, but raised by cobalt.

The A_2-arrest is reversible, and ferromagnetic α-iron does not show the phenomenon of superheating, nor does the paramagnetic β-iron show the phenomenon of under-cooling. The ultimate molecular or atomic particles concerned in ferromagnetism, even though they are in an intense magnetic field, acquire more and more violent thermal oscillations as the temp. rises. This destroys the orientations of these particles imposed by the magnetic field. The most rapid loss in magnetic susceptibility or permeability occurs at about 768°, the A_2-arrest, and thereafter the ferromagnetism continues to decrease, so that the last detectable traces have vanished completely at about 790°. Energy must be expended in breaking up the orientation of the molecular or atomic magnets, so that there is a marked change in the heat content or sp. ht. at the A_2-arrest. There is also a change in the thermo-electric power and electrical resistance at the A_2-arrest. There is also a slight expansion at this temp., possibly associated with magnetostriction. The fact that the principal physical properties which are changed at the A_2-arrest are magnetic and electrical led M. Geiss and J. A. M. van Liempt to suggest that the changes in the space-lattice are electronic not atomic ; but from a study of the K-emission spectra F. Wever could not detect any difference in the electronic configuration of the outer shell of magnetic and non-magnetic iron atoms. D. Jones, and F. Wever also discussed the electronic structure of the two phases.

The A_3-point.—O. L. Roberts and W. P. Davey considered 907° to 910° to be best representative value for this temp. The mean temp. between the Ac_3- and the Ar_3-arrests represents the point above which iron exists in the γ-form, and below which it exists in the paramagnetic α-form, *i.e.* the β-form. A. Sauveur found that the A_3-arrest depends on the previous thermal history of the specimen, for the Ac_3-point on a first heating was 850°, and on the eleventh heating, 919° ; E. Maurer, that the Ar_3-arrest is lowered from 865° to 830° when the rate of cooling is increased from 15 to 280 degrees per minute ; and R. Ruer and F. Goerens, that it is lowered from 900° to 892° when the rate of cooling is increased from 1 to 12 degrees per minute. Analogous results were obtained by F. Wever and N. Engel. O. L. Roberts found that with purified iron the face-centred cubic lattice persists at 921°. A. M. Portevin and M. Garvin, W. Schneider, F. Wever and A. Heinzel,

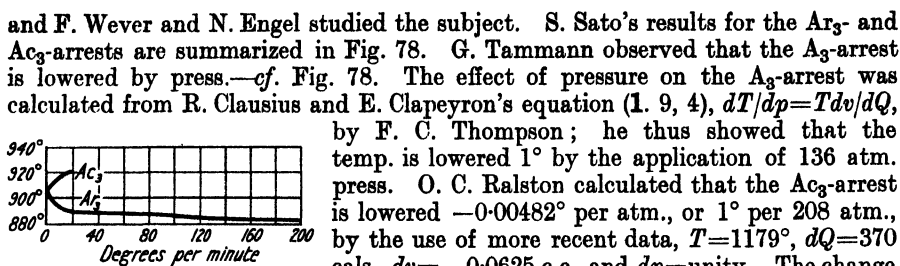
and F. Wever and N. Engel studied the subject.   S. Sato's results for the Ar_3- and Ac_3-arrests are summarized in Fig. 78.   G. Tammann observed that the A_3-arrest is lowered by press.—*cf.* Fig. 78.   The effect of pressure on the A_3-arrest was calculated from R. Clausius and E. Clapeyron's equation (1. 9, 4), $dT/dp=Tdv/dQ$,


FIG. 78.—The Effect of Rate of Heating or Cooling on the A_3-arrests.

by F. C. Thompson; he thus showed that the temp. is lowered $1°$ by the application of 136 atm. press.   O. C. Ralston calculated that the Ac_3-arrest is lowered $-0.00482°$ per atm., or $1°$ per 208 atm., by the use of more recent data, $T=1179°$, $dQ=370$ cals., $dv=-0.0625$ c.c., and $dp=$unity.   The change in the *microstructure* of iron as it passes through the A_3-arrest was studied by T. Andrews, H. C. H. Carpenter, B. A. Rogers, D. Ewen, H. Hanemann, J. C. W. Humfrey, A. Kroll, P. Oberhoffer and A. Heger, H. S. Rawdon and co-workers, W. C. Roberts-Austen, W. Rosenhain and co-workers, E. H. Saniter, F. Sauerwald and co-workers, A. Sauveur and C. H. Chou, J. E. Stead and co-workers, O. W. Storey, F. Wever, and T. D. Yensen.   B. A. Rogers said that the change in microstructure which takes place at the A_3-arrest, between $899°$ and $912°$, occurs as an eruption wave which passes quickly over the surface and leaves it completely changed in appearance.   No change in the micro-structure of armco iron and of electrolytic iron which has been melted in vacuo occurs below the A_3-point.   The nature of the *crystalline change* in passing through the A_3-arrest was first studied by F. Osmond, and F. Osmond and G. Cartaud, and it is discussed in a special section below.   The changes in the *mechanical properties* at the A_3-arrest were discussed by J. C. W. Humfrey, F. C. Lea, W. Rosenhain, W. Rosenhain and J. C. W. Humfrey, and J. E. Stead—*vide infra.*   F. Sauerwald and T. Sperling found that the Ac_3-arrest can be lowered $4°$ and the Ar_3-arrest raised $4°$ by mechanical strain.   Numerous observations have been made on the location of the A_3-arrest by *heating and cooling* curves, by F. Osmond, J. O. Arnold, G. Belloc, W. Broniewsky, G. Charpy, G. Charpy and L. Grenet, W. Gontermann, E. Heyn, P. Oberhoffer, W. C. Roberts-Austen, and W. Rosenhain and J. C. W. Humfrey.   R. Ruer and K. Bode place the Ar_3-arrest at $875°$ and the Ac_3-arrest at $880°$; R. Ruer and K. Fick gave $875°$ for the Ar-arrest, R. Ruer and F. Goerens gave $906°$ for the A_3-arrest; K. Honda and H. Takagi gave $916°$ for the Ac_3-arrest and $890°$ for the Ar_3-arrest; and H. Masumoto gave $908°$ for the Ac_3-arrest and $888°$ for the Ar_3-arrest; F. Wever and K. Apel gave $905°$ for the Ac_3-arrest, and $855°$ for the Ar_3-arrest; A. Perrier and F. Wolfers gave $A_3=900°$; A. Sanfourche, $Ac_3=959°$ and $Ar_3=877°$; P. Bardenheuer, $Ac_3=911°$ and $Ar_3=886°$; F. C. Thompson, $Ac_3=920°$; A. Müller, $Ac_3=917°$ and $Ar_3=984°$; H. C. H. Carpenter and B. F. E. Keeling, $Ac_3=908°$ and $Ar_3=901°$; J. E. Stead and H. C. H. Carpenter, $Ac_3=920°$ and $Ar_3=887°$; and A. Sauveur, $Ac_3=915°$ and $Ar_3=983°$.   G. K. Burgess and J. J. Crowe obtained by extrapolation from the results with different rates of heating $Ac_3=909°$ and $Ar_3=898°$—mean$=903.5°$. K. Honda and S. Miura observed that the transformation takes place through a range of temp. and is not to be regarded as a point—*vide infra.*   H. Quinney found that the difference in the fall of temp. between single crystals and polycrystals at the Ac_3-arrest is about $4°$, and the result is explained by the existence of surface energy at the crystal faces of polycrystalline iron.   Indeed, it was found that mechanical overstrain, which leads to a breaking up of the crystals, reduces the heat absorption at the critical point, owing to an increase in the surface area of the crystals.   J. E. N. Pionchon, J. Maydel, and F. K. Bailey also observed breaks corresponding with the A_3-arrest on the *specific heat* curves.   F. Wüst and co-workers showed with electrolytic iron that the Ac_3-break occurs at $919°$ and the Ar_3-break at $911°$; J. A. Harker observed a break at $900°$; A. Meuthen, one at $890°$; P. N. Laschtschenko, one at $895°$; and P. Oberhoffer and W. Grosse, and S. Umino, a break at $906°$.   W. Broniewsky, G. Charpy, P. Chevenard, J. Driesen,

and J. E. Stead and L. Grenet observed singularities corresponding with the A_3-arrest in the *thermal expansion* curve; that of C. Benedicks gave a marked change in vol. for Ac_3-arrest at 903° to 906°. These changes may be due to the relief of strains which attend recrystallization; the sharpness of the transformation made C. Benedicks assume that α- or β-iron is insoluble in γ-iron, but P. Chevenard found that there is an interval of temp. indicating that β-iron is soluble in γ-iron. H. Esser obtained results in agreement with $Ac_3=906°$ and $Ar_3=897°$; S. Konno, $Ac_3=903°$; and S. Sato, $Ac_3=895°$ and $Ar_3=885°$—or eliminating the effects of the rate of cooling, $A_3=903°$. K. Honda and S. Miura found that the Ac_3-arrest of armco iron occurs at 860° to 905°, and the Ar_2-arrest, at 889° to 850°. Observations by O. Boudouard, W. Broniewsky, H. le Chatelier, P. Fournel, A. R. Meyer, and D. K. Morris showed that there are discontinuities in the *electrical resistance* curve corresponding with the A_3-arrest. G. K. Burgess and I. N. Kellberg found singularities corresponding with the Ac_3-arrest between 900° and 911°, and with the Ar_3-arrest between 887° and 872°; and I. Iitaka, for $Ac_3=950°$ and $Ar_3=910°$. Singularities were observed by P. Saldau, G. Belloc, C. Benedicks, W. Broniewsky, R. Durrer, and E. B. Harrison in the curve for the *thermoelectric force*. G. K. Burgess and H. Scott found singularities corresponding with the Ac_3-arrest between 906° to 916°, and with the Ar_3-arrest between 900° and 896°; P. Oberhoffer, with $Ac_3=909°$ and $Ar_3=895°$; whilst A. Goetz observed singularities in the range 900° to 910°. J. F. T. Berliner obtained similar results. Irregularities were observed by P. Curie, K. Honda and co-workers, and P. Weiss and co-workers in the *magnetic susceptibility* curves. K. Honda and H. Takagi found singularities corresponding with the Ac_3-arrest at 908° to 911°, and for the Ar_3-arrest, 889° to 898°; T. Ishiwara similarly obtained singularities for the Ac_3-point at 898° and for the Ar_3-point at 890°; T. D. Yensen, Ar_3 at 894°; and E. M. Terry, at 918° for the Ac_3-point and at 903° for the Ar_3-point. G. Belloc, A. Sieverts, and E. Jurisch observed singularities in the *solubility of hydrogen* in iron corresponding with the A_3-arrest; P. van Groningen, in the *equilibrium constant* of the system α—Fe—FeO—γ—Fe—gas; and A. B. Bagdasarian, in the equilibrium constant of the reaction: $FeCl_2+H_2 \rightleftharpoons 2HCl+Fe$.

A. E. Oxley, G. Mars, L. Grenet, and T. D. Yensen inferred that if iron could be completely purified, it would be found to exist only in the α-form. It is assumed that pure iron, below the m.p., has no allotropic forms, and its characteristic lattice structure is the body-centred cube; it is further assumed that the A_3- and A_4-transformations are caused by the entrance of carbon and other " stranger " atoms in the interstitial spaces of the lattice; and when their amount exceeds the solubility in α-iron at the particular temp., they cause the iron to modify its structure in order to accommodate them. The γ-phase is suppressed in the iron-silicon alloys when the proportion of silicon exceeds 1·5 to 2·5 per cent., and this amount of silicon represents what is required to deoxidize the iron; otherwise silicon is not an interstitial element so far as the space-lattice is concerned, rather is it a substitution element. Similarly with the alloys with chromium (*q.v.*). The subject was discussed by F. C. Thompson, R. A. Hadfield, J. E. Stead and H. C. H. Carpenter, and G. K. Burgess and I. N. Kellberg.

The A_4-point.—This corresponds with the appearance of a new phase called δ-iron. As indicated above, this transition point was discovered by E. J. Ball; and it was discussed by F. Wever, P. Weiss, J. O. Arnold, W. Rosenhain, F. Osmond, R. Ruer and co-workers, M. Copisarow, H. Bredmeier, K. Honda, and H. le Chatelier. The effect of pressure on the A_4-arrest, calculated as in the case of the A_3-arrest, is to raise the Ac_4-point 0·00557° per atm. or 1° per 180 atm. when $T=1673°$, $dQ=140$ cals., $dv=0·0192$ c.c.; $dp=$unity. The change in the *microstructure* was examined by F. Wever, F. Sauerwald and co-workers, and H. S. Rawdon and T. Berglund. E. J. Ball, and F. Osmond observed by the *heating and cooling* curves that the Ar_4-arrest occurs at about 1300°, and more accurate observations by W. Gontermann gave 1411°; R. Ruer and K. Fick, and R. Ruer and K. Kaneko observed 1420°;

R. Ruer and R. Klesper, 1401°; and D. Hanson and J. R. Freeman, 1400°. The subject was also studied by W. C. Roberts-Austen, H. Harkort, A. Müller, and A. Sanfourche. The *specific heat* curves of F. Wüst and co-workers showed a singularity at 1404·5°; and those of P. Oberhoffer and W. Grosse, at 1401°. J. Maydel made observations on the subject. S. Sato, and P. Chevenard examined the *thermal expansion* curves and found a break corresponding with A_4=1400°. S. Sato said that the expansion curve of δ-iron is continuous with that of α-iron, and hence inferred that α- and δ-irons are the same allotrope. P. Oberhoffer found a discontinuity in the curve for the *thermoelectric force* at 1403°, and A. Goetz, one at 1400°. The *magnetic susceptibility* curves of P. Curie gave the transition at about 1390°; P. Weiss and G. Foëx observed a singularity at 1395°; T. Ishiwara, at 1390°; and E. M. Terry, at 1406°. A. Sanfourche observed 1360° on the heating and 1310° on the cooling curves. A. Goetz observed a change in the *emission of electrons* between 1400° and 1500°; and A. B. Bagdasarian, a change in the *equilibrium constant* for the reaction $FeCl_2 + H_2 \rightleftharpoons 2HCl + Fe$.
FIG. 79.—The Effect of the Atomic Volume of the Alloying Element on the γ-Phase.

Most elements have an opposite effect on the A_4- and A_3-arrests. Thus, the addition of chromium lowers the A_4-arrest and raises the A_3-arrest, so that the range of stability of the γ-phase becomes smaller and smaller, until it finally disappears. This occurs with about 14 per cent. of chromium. The curves for the A_3-, A_4-arrests meet at 1075°, and γ-iron does not exist in alloys with more chromium. The A_3- and A_4-arrests are suppressed. Similar results are obtained with about 6 per cent. of tungsten, or 1·85 per cent. of silicon, or 2 per cent. of tin, or 2·5 per cent. of vanadium; and aluminium, molybdenum, and phosphorus act similarly and narrow the field of stability of γ-iron. On the other hand, the reverse effect is produced by carbon, copper, and nickel. These elements thus enlarge the field of stability of γ-iron. The A_4-arrest is raised from 1400° to 1477° by 8 per cent. of copper, and the A_3-arrest is lowered 833° by 3 per cent. of copper; the A_4-arrest is raised to 1502° by 3·2 per cent. of nickel, and the A_3-arrest is lowered to room temp. by 36 per cent. of nickel; whilst the A_4-arrest is raised to 1486° by 0·38 per cent. of carbon, and the A_3-arrest is lowered to 730° by 0·9 per cent. of carbon. Cobalt is peculiar in that it does not produce opposite effects on the A_4- and A_3-arrests. Thus the presence of 22 per cent. of cobalt raises the A_4-arrest to 1492°, and the

A_3-arrest is raised to 990° by 45 per cent. of cobalt. F. Wever showed that the elements Mn, Ni, Co, Ru, Rh, Pd, Os, Ir, and Pt enlarge the temp. range of stability of the γ-phase, whilst the elements Be, Al, Si, P, Ti, V, Cr, Ge, As, Cb, Mo, Sn, Sb, Ta, and W narrow the range of stability of the γ-phase. All this is in accord with F. Osmond's rule that elements with a small at. vol. tend to produce in iron that form which has the smallest at. vol.—*i.e.* γ-iron. Boron and beryllium are exceptional. J. O. Arnold, and H. von Jüptner thought that the alleged allotropic changes were largely due to the presence of impurities—notably hydrogen. The effect of hydrogen on the A_3-arrest was examined by H. le Chatelier ; and L. Guillet and A. M. Portevin could detect no marked influence of hydrogen on the A_3-arrest. For the effect of hydrogen on the A_2-arrest, *vide supra*. The effect of elements of different at. vol. in relation to the at. number is shown in F. Wever's tables, Fig. 79, where ▲ denotes that the element is virtually insoluble; ●, that the element narrows the range of the γ-phase ; and ■, that the element widens the range of the γ-phase. An analogous curve is produced by plotting the at. radius and at. number. The relation between the effects produced by elements and their position in the periodic

FIG. 80.—The Effect produced by Different Elements Grouped in Accord with the Periodic Table.

table is indicated in Fig. 80. A. Merz found that chromium lowers the A_3-arrest, tungsten raises the temp., silicon, and nickel broaden the γ-field, and manganese has little effect.

The X-radiograms of A. W. Hull, and A. Westgren show that the α- and δ-forms of iron have the same body-centred cubic lattice, whilst the γ-form of iron has a face-centred cubic lattice. Observations on the temp. coeff. of the thermoelectric force by W. Schneider, A. Goetz, and G. K. Burgess, the magnetic susceptibility by P. Weiss and G. Foëx, and the sp. ht. by P. Oberhoffer and W. Grosse show that the curves for the α- and δ-forms of iron would be continuous were they not disturbed by the intervention of the γ-phase ; and, as just indicated, this phase can be suppressed. F. Wever therefore suggested that α- and δ-iron are one and the same phase.

At first sight it seems thermodynamically improbable that at one temp. an allotrope A should pass into an allotrope B with the evolution of heat, and that at a higher temp. the allotrope B should return to the original allotrope A, again with an evolution of heat. H. Bredemeier showed that there may be a thermodynamic reason for this strange phenomenon. He said that if it were possible to plot the

thermodynamic potential ζ, or free energy of one form, and compare it with that of the other, the two curves would present the appearance of those in Fig. 81 (ζ, arbitrary scale). The curve ab would be the isobaric curve of the thermodynamic potential of α- and δ-iron, and cd, the same for γ-iron. Their intersections at 906° and 1400° are the transition temp. The form of iron with the smallest potential is the most stable, and this is the case for γ-iron between 906° and 1400°. Thermodynamic potential ζ is a measure for the stability of a phase, and it can be represented as a function of the free energy, E, and the entropy, S, so that $\zeta = E - TS + pv$, where p, v, and T respectively denote the press., vol., and temp. The entropy is the first derivative of the free energy, so that $S = d\zeta/dT$, whilst the second derivative is a function of the sp. ht., so that $d^2\zeta/dT^2 = -C_p/T$. By comparing the slopes, $d\zeta/dT$, of the curves at 906° and
FIG. 81.—The Thermodynamic Potential of Iron (Diagrammatic).

1400°, Fig. 81, it follows that at 906° the thermodynamic potential of α-iron is greater than that of γ-iron, whilst at 1400° the thermodynamic potential of γ-iron is greater than that of δ-iron. The energy contents of the two forms of iron can be compared at these two temp., and it follows that in passing from α- to γ-iron the heat of transformation is positive, as is also the case in passing from γ- to δ-iron. The curvature $d^2\zeta/dT^2$ of the curve for γ-iron is less than that of the α-, δ-iron curve, and this would mean that the sp. ht. of γ-iron is the smaller. The sp.

ht. data available do not show this, for while the sp. ht. of γ-iron is less than that of α-iron, it is greater than is that of δ-iron. The sp. ht. data of F. Wüst, however, make the sp. ht. of γ-iron smaller than of both the α- and δ-forms of iron. E. Rengard discussed the theory of cooling curves; and F. H. Jeffery, and Y. Chu-Phay, the thermodynamics of the system; and U. Dehlinger, the changes in the electronic systems in passing from one allotropic form to another.

There is a general agreement that the A_4- and A_3-arrests represent allotropic changes, but there is a difference of opinion about the existence of β-ferrite as an allotropic form of iron. It may represent (i) a veritable allotropic change from a β- to an α-allotrope of iron; (ii) it may not be an independent phase, but rather a solid soln. of α- and γ-ferrites; or (iii) it may represent an intermolecular, not an allotropic change, taking place within a considerable range of temp. in the α-phase.

G. K. Burgess thus compared the evidence for the existence of allotropic transformations of purified iron at the A_2- and A_3-points :

	A_2-arrest	A_3-arrest
Heat evolution or absorption	Present ; $Ar_2 = Ac_2$	Present ; $Ar_3 < Ac_3$
Specific heat . . .	Present ; $Ar_2 = Ac_2$	Present
Electrical resistance .	Marked ; $Ar_2 = Ac_2$	Present
Magnetic susceptibility .	Marked ; $Ar_2 = Ac_2$	Very feeble
Other magnetic properties	Most are well-marked	Most are feeble
Mechanical properties .	Probable	Marked
Expansion	Present	Marked
Crystalline structure (X-rays) .	Body-centred cube	Face-centred cube

and in Table IX A. Sauveur summarized the chief properties of three of the allotropes of iron, for iron containing carbon. According to F. Osmond :

TABLE IX.—A COMPARISON OF SOME PROPERTIES OF ALLOTROPES OF IRON.

	γ-Iron	(β-Iron)	α-Iron
Metallurgical name .	Austenite	β-ferrite	Ferrite; α-ferrite; or pearlite ferrite
Stability range .	Over A_3, $A_{3,2}$ or $A_{3,2,1}$ for excess ferrite; over A_1 or $A_{3,2,1}$ for eutectoid ferrite	Between A_3 and A_2	$A_{3,2,1}$
Crystallization system .	Cubic	Cubic	Cubic
Habit	Octahedra	Cubes	Cubes
Space-lattice .	Face-centred	Body-centred	Body-centred
Twinning . .	Frequent	None	None
Sp. gr. . . .	$>β$- or α-iron	$>α$-iron	$<γ$- and β-iron
Electrical conductivity .	$<α$-iron	$>γ$-iron	$>β$-iron
Magnetic property .	Non-magnetic	Feebly magnetic	Strongly magnetic
Hardness . .	$<β$-iron, $>α$-iron	Very hard	Soft

It is difficult to say whether A_2 is an allotropic modification of iron, or whether it is simply the end of the A_3-transformation retarded by the presence of a little carbon.

The main arguments against the assumption that there is no formation of an allotropic β-iron at the Ar_2-arrests are thus summarized by A. Sauveur:

(i) C. Benedicks, and H. C. H. Carpenter said that the Ac_2-point does not occur with purified iron, but G. K. Burgess and J. J. Crowe do not agree. (ii) H. le Chatelier, and C. Benedicks held that the A_2-arrest does not represent an allotropic change because of the absence of hysteresis between the Ac_2- and Ar_2-arrests. This involves the unjustified assumption that the absence of this phenomenon proves that no allotrope is formed. (iii) No crystallographic change can be detected at the A_2-arrest. This involves the unjustified assumption that no two allotropes can have the same crystallographic form. (iv) The absence of dilation as iron cools through the Ar_2-arrest is supposed by G. Charpy and L. Grenet, and by C. Benedicks to prove the absence of a β-allotrope. This assumes that allotropic changes must be accompanied by changes in vol., and that the measurements so far made are decisive. This is by no means the case; indeed, W. Rosenhain and J. C. W. Humfrey reported a dilation to occur. (v) Although a marked change in the magnetic properties occurs at the A_2-arrest, H. le Chatelier, P. Weiss, K. Honda, C. Benedicks, etc., hold that the A_2-change is not sufficiently abrupt to agree with an allotropic transformation, and that magnetic transformations do not generally indicate allotropic changes. It is argued that the Ac_2-arrest marks the end of a progressive transformation, and that the Ar_2-arrest indicates the beginning of the reverse change. On the other hand, the beginning and end points of a progressive transformation are not likely to be accompanied by an abrupt evolution or absorption of heat. Whilst a magnetic transformation starts below the A_2-arrest, the marked heat evolution at this temp. indicates a sharp break in the continuity of the process, and this suggests allotropy. (vi) No discontinuity in any of the properties of iron has been observed at the Ar_2-arrest, and therefore the transformation cannot be an allotropic one. The curve of the thermoelectric force of iron and carbon does not exhibit any distinct break at the A_2-arrest. On the other hand, the existence of the Ar_2-arrest indicates a sharp discontinuity in the internal energy; a discontinuity in the magnetic properties does occur about this temp.; W. Rosenhain and J. C. W. Humfrey noted a discontinuity in the dilation, although others have denied this; the same observers noted a discontinuity in the tensile strength; P. Weiss and co-workers, and F. Wüst and co-workers noted a discontinuity in the sp. ht.; and G. K. Burgess and I. N. Kellberg, a discontinuity in the electrical resistance.

C. Benedicks attempted to explain the existence of the A_2-arrest in impure iron, without recourse to allotropy, by assuming that highly purified iron will give no A_2-arrest (vide supra), that the A_2-arrest indicates the end of the A_3-change, and that some γ-iron remains untransformed below Ar_3 because the impurities enable a kind of under-cooling to occur. This means that the alleged β-iron is in reality a metastable solid soln. of γ-iron in α-iron, and in consequence, unless the cooling be very slow, the Ar_2- and the Ac_2-arrests might occur in pure iron without dis-

proving the hypothesis. A similar hypothesis was made by M. Copisarow ; P. Curie thought that some γ-iron is present in β-iron. H. le Chatelier showed that there is no need for these hypotheses ; and K. Honda added that the phenomenon at the A_2-arrest is purely a thermomagnetic effect.

K. Honda also tried to explain the nature of the progressive change in the A_2-transformation, as follows :

It is not a change of atomic configuration, as is the case with an allotropic change, but very probably a gradual change of energy in atoms accompanying the rise of temp. According to the theory of K. Honda and J. Okubo, the gradual diminution of magnetiza- tion with rise of temp. is due to the increasing velocity of rotation of the atoms about their magnetic axes. The angular velocity of this rotation is assumed to be comparatively small at room temp., and the gyrostatic resistance to the turning of the magnetic axes of the atoms in the direction of the field is very small. But as the temp. is continuously increased to a very high degree, the angular velocity, by virtue of thermal impact among atoms, always becomes greater, and hence the gyrostatic action of the atoms rapidly increases, the substance becoming thereby less and less magnetizable, till magnetization vanishes. Here it is to be assumed that when the field ceases to act, the direction of the magnetic axes takes a distribution uniform in all directions by virtue of thermal impact. Thus, according to this theory, the A_2-transformation is of the progressive nature and the change will obviously be a definite function of temp., as actually observed. The heat absorbed during the Ac_2-transformation is the energy required to increase the angular velocity of the atoms, while the heat evolved during the Ar_2-transformation is the energy of rotation liberated. F. Osmond later gave up this hypothesis, for he said that β-iron is hard and brittle at ordinary temp., while α-iron is soft ; and since the A_2-arrest, and not the A_3-arrest, corresponds with the loss of magnetism, it follows that there are at least three distinct allotropic forms of iron, namely α-, β-, and γ-ferrites with ranges respectively from 0° to 760° ; 760° to 900° ; and 900° to 1505°.

G. Tammann, G. K. Burgess and H. Scott, H. M. Howe, F. Osmond, W. Rosenhain and J. C. W. Humfrey, R. Ruer, R. Ruer and K. Bode, and A. Sauveur also favoured that assumption that β-ferrite is an allotropic form of iron. J. E. Stead and H. C. H. Carpenter said that the phenomena attending the recrystallization of electrodeposited iron are more readily explained by assuming that at the Ar_2-arrest iron changes directly from the γ- to the α-state. According to C. Benedicks, β-ferrite is really a solid soln. of γ-ferrite in α-ferrite, so that as iron cools beyond the A_3-arrest γ-ferrite passes into α-ferrite, but the change is not complete, a certain proportion of γ-ferrite persists in solid soln. in α-ferrite until the A_2-arrest is reached when the change into α-ferrite is completed. H. C. H. Carpenter showed that the A_2-point become lsess and less marked as the degree of purity of the iron is increased, until a sample with 99·967 per cent. Fe, and 0·008 per cent. C, showed the A_2-point only faintly. A. Müller, G. K. Burgess and J. J. Crowe, J. O. Arnold, and A. Sauveur observed that the Ar_2- and Ac_2-points persist even with iron of an ex- ceptionally high degree of purity. J. O. Arnold found that the Ar_3-point occurs within narrower limits of temp., and more sharply when hydrogen and other occluded gases are absent. In no case, however, has it been possible to eliminate the Ar_3- and Ar_2-points by heating iron of a high degree of purity in vacuo. He inferred that the Ar_3-temp. is not connected with the Ar_2-arrest ; and that the Ar_3- temp. represents the physical change of hot iron from the plastic to the crystalline state.

It is very clear that the A_2-arrest represents the temp. of magnetic transforma- tion where ferromagnetic iron becomes paramagnetic. This temp. is often called *Curie's point.* Consequently, β-iron can be regarded as non-magnetic α-iron, ordinary α-iron being magnetic. It is very well established that both paramagnetic and ferromagnetic α-iron have the same crystalline structure—a body-centred, cubic space-lattice—whilst there is a break in the continuity of some physical properties as the metal passes through the A_2-arrest. The fact that the A_2-transformation occurs not so much at a definite and sharply-defined temp. as within a certain range of temp. is of no significance when it is remembered that K. Honda and S. Miura, and G. K. Burgess and co-workers proved that the same phenomenon is characteristic of the A_3-arrest—*vide* nickel-iron alloys. It has been suggested that since no

crystalline change occurs at the temp. of magnetic transformation the term allotropic change should not be employed. Thus, H. le Chatelier said :

Le phénomène tout-à-fait différent des transformations allotropiques ordinaires. Je suis de plus en plus convaincu que la différence entre le fer α et le fer β n'est pas une différence d'état allotropique, comme entre le fer γ et les variétés stables à froid. Tous les corps magnétiques, sans aucune exception, présentent, à une certaine température, le même chute progressive des propriétés magnétiques. C'est un phénomène caractéristique des corps magnétiques et seulement de ceux-là.

P. Weiss, from magnetic considerations, thought that the α- and β-states are not different phases ; K. Honda and Y. Okura obtained a pronounced break in the resistance-temperature curve, but even then did not consider the A_2-arrest to be the seat of an allotropic transformation ; and a similar conclusion was drawn by L. Grenet, C. A. Edwards, L. Guillet and A. M. Portevin, K. Honda and co-workers, R. A. Hadfield, F. Wüst and co-workers, T. Ishiwara, F. Wever, H. le Chatelier, P. Weiss, A. E. Oxley, E. Maurer, H. C. H. Carpenter, and C. Benedicks.

The attempt is made to evade the definition which commonly applies the word *allotropy* to the various states of an element or compound possessing different physical properties. It is objected that the term " different physical properties " is vague ; and that is certainly the case if it implies the right to include one or more physical properties so as to make any given phase an allotrope of the same element or compound. Consequently, to ignore isomorphism, and use the term polymorphism in place of allotropy, does not answer the real question behind the words : " Is β-iron an allotropic modification of iron ? " or " Does the A_2-arrest indicate that the iron is undergoing an allotropic change ? " We are quite at liberty to make any definition we please, so as to be able to affirm or deny that β-iron is an allotropic form of iron. The subject was discussed by M. Copisarow, K. Honda, C. Benedicks, C. H. Desch, A. E. Oxley, F. C. Thompson, A. Sauveur, etc. We are in quite a similar predicament in answering the question : Are solutions chemical compounds ? (**1.** 2, 9 ; and **1.** 9, 5). Indeed, we are frequently perplexed with a similar type of question. F. Wever and P. Giani said a change of phase can be characterized by a discontinuous change in suitable physical properties, but not necessarily by all physical properties of the substance involved. A polymorphic change or transformation applies only to crystalline substances and is characterized by a discontinuous change in the space-lattice which can now be realized without difficulty. A change in crystalline form is usually accompanied by changes in physical properties so that a polymorphic change is always a change of phase. O. C. Ralston inquired : Is a change of phase always a polymorphic change ? and added that β-iron, or non-magnetic α-iron, has enough difference in physical properties and internal energy to deserve recognition even though there is no satisfactory word or definition to express the difference. In any case, β-iron or β-ferrite can be understood to mean that particular phase of iron which exists between the A_2- and A_3-arrests.

P. G. Tait inferred that iron becomes as it were a different metal on being raised above a certain temp., and he said that this may possibly have some connection with the *ferricum* and *ferrosum* of the chemists. J. N. von Fuchs said there are two species of iron, and he suggested that malleable iron consists of cubic crystals, and cast iron of rhombohedral crystals. He thus foreshadowed the assumption that iron exists in allotropic forms, although his reasons for assuming these varieties were utterly inadequate. A. Baudrimont's *Observations sur la constitution intime du fer* were to the same effect as those of J. N. von Fuchs. Now for the world of speculation. P. Weiss suggested that the molecules of δ-ferrite are monatomic ; those of γ-ferrite, diatomic ; and those of β-ferrite, triatomic. K. Honda and H. Takagi, however, do not agree. A. E. Oxley referred the differences in the allotropic forms of iron to differences in the grouping of the atoms ; M. Copisarow, to differences in the number of atoms in the molecule ; and D. Jones, to changes in the atoms of iron.

§ 13. The Microstructure of Iron and Steel

Numerous examples of the microstructure of iron and steel are indicated below. The history of the subject of *metallography*, the study of the minute structure of metals, commenced seriously after the work of H. C. Sorby [1] on the microstructure of steel. His idea was that a close analogy obtains between the constitution of steel and of a crystalline igneous rock : " Steel," said he, " must be regarded as an artificial crystalline rock, and to get a complete knowledge of it, it must be regarded as such." The general subject has been discussed by C. H. Desch, L. Guillet, and others. Many papers and books have also been written on the preparation of specimens for microscopic examination. For example :

H. Behrens, *Das mikroskopische Gefüge der Metalle und Legierungen*, Hamburg, 1894 ; A. H. Hiorns, *Metallography*, London, 1902 ; U. le Verrier, *Ann. Conservatoire Arts Métiers*, (2), **9**. 121, 1896 ; J. T. Milton, *Trans. Inst. Marine Eng.*, **14**. 101, 1902 ; E. Heyn, *Verh. Ver. Beförd. Gewerbefleisses*, **83**. 355, 1904 ; H. Wedding, *ib.*, **65**. 203, 1886 ; R. K. B. Wild, *Prof. Papers Roy. Eng.*, **30**. 207, 1904 ; O. Boudouard, *Bull. Soc. Chim.*, (3), **1**, 1906 ; R. Ruer, *Metallographie in elementarer Darstellung*, Hamburg, 1907 ; P. Goerens, *Einführung in die Metallographie*, Halle a. S., 1922 ; London, 1908 ; W. Guertler, *Metallographie*, Berlin, 1909 ; *Metallurgie*, Berlin, 1923 ; C. H. Desch, *Metallography*, London, 1910 ; L. Révillon, *La métallographie microscopique*, Paris, 1910 ; F. Robin, *Traité de métallographie*, Paris, 1912 ; W. T. Hall and R. S. Williams, *The Chemical and Metallographic Examination of Iron, Steel, and Brass*, New York, 1921 ; W. Fraenkel, *Leitfaden der Metallurgie mit besonderer Berück sichtigung der physikalisch-chemischen Grundlagen*, Dresden, 1922 ; L. Guillet, *Les méthodes d'études des alliages métalliques*, Paris, 1922 ; L. Guillet and A. M. Portevin, *Précis de métallographie microscopique et de macrographie*, Paris, 1923 ; F. L. Garrison, *The Microscopic Structure of Iron and Steel*, London, 1886 ; F. Osmond, *Sur la cristallographie du fer*, Paris, 1900 ; London, 1904 ; *Ann. Mines*, (9), **17**. 110, 1900 ; *Ordnance Bur. U.S. War Dept.*, 68, 1893 ; *Microscopic Metallurgy*, London, 1893 ; S. A. Houghton, *Trans. Inst. Marine Eng.*, **14**. 101, 1902 ; H. von Jüpter, *Ver. Verbreit. Naturw. Kenntnisse*, **45**. 113, 1904 ; H. Savoia, *Metallografia applicata ai prodotti siderurgici*, Milano, 1909 ; London, 1910 ; O. Kröhnke, *Kurze Einfuhrung in den innern Gefügeaufbau der Eisenkohlenstofflegierungen*, Berlin, 1911 ; A. Martens, *Stahl Eisen*, **12**. 672, 1892 ; **15**. 954, 1895 ; *Mitt. tech. Versuchanst.*, **11**. 347, 1894 ; *Verh. Ver. Eisenbahnkunde*, 67, 1892 ; A. Sauveur, *The Metallography and Heat Treatment of Iron and Steel*, Cambridge, Mass., 1926 ; H. M. Howe, *The Metallography of Steel and Cast Iron*, New York, 1916.

In developing the structure of a heterogeneous solid for microscopic examination, the differences in the constituents can be emphasized by taking advantage of the fact that some are harder than others, so that when the surface is polished, the softer constituents are worn away to a greater depth, and the harder constituents appear in relief when the polished surface is viewed by oblique illumination. The polishing may be varied by using a suitable liquid which acts preferentially on some constituents more than others. The process is referred to as the **polish-attack** or **polish etching.** F. Osmond rubbed the surface on a piece of stretched parchment soaked in an aq. extract of liquorice and calcium sulphate ; and later, F. Osmond and G. Cartaud used a 2 per cent. aq. soln. of ammonium nitrate. If the surface be heated in a suitable atmosphere—say air—the rate of oxidation of the different constituents varies, so that films of different thicknesses and colorations are produced. These exhibit characteristic effects under the microscope. This method of developing the structure is called **heat tinting,** or **heat relief.** It was employed by F. Osmond, W. C. Roberts-Austen, C. Benedicks, N. Gutowsky, P. Breuil, P. Oberhoffer and co-workers, F. Sauerwald and co-workers, P. Goerens and co-workers, J. E. Stead, G. Tammann and G. Siebel, F. Robin, J. Czochralsky, F. Reiser, L. Löwenherz, T. Turner, and H. Haedicke.

Chemical methods of **etching** are more frequently employed. Here the different constituents are attacked by suitable reagents at different rates—*vide* Table X.

TABLE X.—THE ETCHING OF THE CONSTITUENTS OF IRON-CARBON ALLOYS

Constituent	Polish attack	Iodine	Nitric acid	Remarks
Ferrite	Granular	Colourless	Polygonal structure	Softer than other constituents; coloured by nitric acid, while cementite is not.
Cementite	Nil	White	No action in 40 sec. with 20 per cent. acid	Harder than other constituents; not coloured by nitric acid, while ferrite is.
Martensite	Intersecting needles appear	Coloured slowly	Yellowish	Unlike pearlite, has straight intersecting fibres.
Pearlite	Curved lamellæ	Dark	Dark	Unlike martensite, fibres are curved and never intersecting.
Troostite	Yellow brown to blue bands	Coloured faster than martensite	Dark yellow	Accompanies martensite, and is coloured more slowly than sorbite.
Sorbite	Coloured	Coloured faster then troostite	Dark	Accompanies pearlite, and is coloured more quickly than troostite.
Austenite	Nil	Coloured	Lighter yellow than martensite	Martensite goes yellow, brown, and black when treated by electro-chemical attack.

The rate of attack was studied by L. Loskiewicz. In 1772, J. J. Perret proposed testing Damascus steel by etching; in 1781, T. Bergman distinguished iron from steel by etching with sulphuric acid; in 1850, E. Clark used etching to distinguish between hand and machine riveting; in 1872, M. van Ruth tested the character of iron by etching; in 1873, F. Kick used etching to show the structure of welded iron; in 1878, A. R. von Kerpely studied the structure of iron and steel by the etching process; and later A. Ledebur, O. F. Hudson, S. Stein, H. Wedding, and A. Martens discussed the subject. L. von Tetmajer, W. C. Roberts-Austen, and O. Wawrziniok emphasized the importance of etching tests for rail-steel. General observations were made by W. Campbell, H. S. Rawdon, E. C. Groesbeck, W. Guertler, W. Ast, C. Frémont, etc. Many reagents have been recommended for special alloys.

Hydrochloric acid—H. le Chatelier, F. Osmond, F. Osmond and J. E. Stead, N. M. von Wittorf, W. Ast, C. Frémont, C. F. Comstock, F. P. Gilligan and J. J. Curran, A. Fry, B. Strauss and A. Fry, E. Heyn, O. Ruff and W. Martin, A. Jung, and P. Goerens and K. Ellingen. F. Osmond recommended a 10 per cént. aq. soln. of hydrochloric acid. E. Heyn and A. Martens employed a soln. of 1 c.c. of hydrochloric acid of sp. gr. 1·19 in 120 c.c. of absolute alcohol. H. le Chatelier used a soln. of hydrochloric acid in glycerol; and F. W. Spiller recommended a gram of nitric acid of sp. gr. 1·42 in 9·9 grms. of glycerol. A. Baykoff exposed the hot steel to the action of hydrogen chloride gas. Sulphuric acid— N. M. von Wittorf, W. Ast, and C. Frémont. F. W. Rowe used a hot, dil. mixture of sulphuric and hydrochloric acids. J. E. Stead recommended 20 per cent. sulphuric acid followed by a cleaning with nitric acid. Sulphurous acid—S. Hilpert and E. Colver-Glauert employed a 3 to 4 per cent. sat. aq. or alcoholic soln. of sulphurous acid. Nitric acid—H. Bell, F. Osmond and G. Cartaud, F. Rinne, N. Parravano, W. C. Roberts-Austen, F. Osmond, J. E. Stead, H. C. Sorby, W. Ast, J. P. Gill and L. D. Bowman, C. Frémont, A. Sauveur, J. O. Arnold, N. M. von Wittorf, W. Campbell, E. Maurer, O. Ruff and W. Martin, O. Mezger and co-workers, and P. Goerens and K. Ellingen. A. Martens used a soln. of 4 c.c. of nitric acid of sp. gr. 1·14 in 100 c.c. of absolute alcohol. H. le Chatelier used a soln. of nitric acid in glycerol. W. J. Kurbatoff recommended a soln. of 20 per cent. nitric acid in 4 parts of amyl alcohol, and this was used with good results by P. Goerens and H. Meyer. W. J. Kurbatoff's reagent A was a 1 per cent. soln. of nitric acid in a mixture of methyl, ethyl and isoamyl alcohols with some acetic anhydride. A mixture of nitric and hydrochloric acids—aqua regia—was employed by F. Osmond and W. C. Roberts-Austen,

and C. Frémont. C. Benedicks and P. Sederholm used an alcoholic soln. of 0·1 per cent. nitric acid. N. B. Pilling used a soln. of nitric acid and methyl alcohol in nitrobenzene for etching carbides in silicon steels. J. R. Vilella used a soln. of **aqua regia** in glycerol for chromium-iron alloys. **Hydrofluoric acid**—L. Baraduc-Müller used a mixture of one part of hydrofluoric acid and two parts of alcohol for silicon alloys ; and it was also employed by F. Dörinckel, and H. le Chatelier. **Iodine solution**—say 10 grms. of iodine, 20 grms. of potassium iodide, and 100 c.c. of water—was used by K. Friedrich, W. C. Roberts-Austen, P. Oberhoffer, E. Heyn, V. N. Svetchnikoff, F. Osmond, H. C. Boynton, C. Benedicks, L. von Tetmajer, W. Ast, and C. Frémont. K. Friedrich also recommended a **solution of bromine** and potassium iodide for dealing with iron and sulphur alloys. O. Ruff and W. Martin used a soln. of 1 c.c. of bromine in 1 c.c. of 8 per cent. hydrochloric acid. H. B. Pulsifer used **chloric acid.**

*Ortho*nitrophenol—four parts in a sat. soln. was mixed with one part of a 4 per cent. soln. of nitric acid as W. J. Kurbatoff's reagent D. An alcoholic soln. was employed by N. T. Belaiew, E. Maurer, and J. Guillemin. *Meta*nitrobenzenesulphonic acid in 4 to 5 per cent. alcoholic soln. was employed by C. Benedicks. **Picric acid** was introduced as W. P. Ischewsky's reagent in 1902, and it is in common use in about 5 per cent. alcoholic soln. The reagent was used by N. Baar, F. Osmond and G. Cartaud, M. Levin and G. Tammann, S. Hilpert, N. Parravano, E. Isaac and G. Tammann, H. le Chatelier, H. le Chatelier and A. Ziegler, F. Robin, J. Kirner, W. Campbell, E. Maurer, G. Röhl, N. M. von Wittorf, L. Guillet, F. Robin and P. Gartner, J. P. Gill and L. D. Bowman, P. Goerens and K. Ellingen, and J. E. Stead. A soln. in acetone was employed by F. Osmond and G. Cartaud for iron-nickel meteorites. H. le Chatelier employed a soln. of picric acid in glycerol. A soln. of **sodium picrate** was recommended for cementite by H. le Chatelier, M. Matweieff, W. J. Kurbatoff, and A. Sauveur and V. N. Krivobok used a hot, 3 per cent. soln. of sodium picrate in an excess of soda-lye. An alcoholic soln. of **salicylic acid** was recommended for pearlite by V. N. Svechnikoff.

Alkali hydroxide was employed by U. Raydt and G. Tammann, and H. le Chatelier, who also recommended a boiling soln. of alkali hydroxide with a small proportion of an oxidizing agent—nitrate, iodate, plumbate, or picrate. H. le Chatelier employed an aq. soln. of potassium hydrotartrate ; or a mixture of equal parts of a 50 per cent. aq. soln. of sodium carbonate and a 10 per cent. aq. soln. of lead nitrate. **Hydrogen dioxide** in ammoniacal soln. was recommended by R. Sahmen, and J. P. Gill and L. D. Bowman. M. Yatsevitch used 10 c.c. of commercial hydrogen dioxide, and 20 c.c. of a 10 per cent. soln. of sodium hydroxide for high-speed tool steels. **Ammonium persulphate** was recommended by J. Czochralsky, and H. S. Rawdon. G. Tammann and co-workers used a 10 per cent. soln. of the salt. F. C. Thompson and E. Whitehead found that a soln. of **ammonium molybdate** will darken cementite.

Ammonium nitrate soln. was used by C. Benedicks and F. Osmond—*vide supra*. **Calcium chloride**—E. H. Saniter recommended immersion in molten calcium chloride. An alcoholic soln. of **potassium ferricyanide** mixed with nitric acid was recommended by G. Gallo, T. F. Russell, T. Murakami and K. Someya, F. C. Thompson and E. Whitehead, C. E. McQuigg, and P. Oberhoffer and co-workers. For chromium and tungsten steels, K. Daeves used a soln. of potassium ferricyanide, 20 grms. ; sodium hydroxide, 10 grms. ; water, 100 grms. T. Murakami recommended a soln. of 10 grms. potassium ferricyanide, 10 grms. of potassium hydroxide, and 100 c.c. of water for the identification of the complex carbides of iron and chromium. **Mercuric chloride** soln., five grams in 100 c.c. of water, was used by C. Frémont. **Copper sulphate** soln. was used by U. Raydt and G. Tammann, G. Tammann and W. Treitschke, A. von Vegesack, W. Guertler, N. M. von Wittorf, and M. Chikashige and T. Hiki. **Ammonium cuprous chloride** in 8 per cent. soln. was used by F. Osmund and G. Cartaud, E. Isaac and G. Tammann, and E. Heyn. **Ammonium cupric chloride**—say 10 per cent. soln.—was used by E. Isaac and G. Tammann, A. M. Portevin, E. Heyn and O. Bauer, O. Bauer and E. Deiss, E. Heyn and A. Martens, G. Preuss, F. Osmond, F. Osmond and J. E. Stead, J. C. W. Humfrey, A. von Dormus, G. Haufe, W. Ast, and C. Frémont. **Cupric chloride**—a soln. of cupric chloride appears in many forms. J. E. Stead used $CuCl_2$, 10 grms. ; $MgCl_2$, 40 grms. ; hydrochloric acid, 10 c.c. ; water, 20 c.c. ; and alcohol to 1000 c.c. The soln. was used by G. F. Comstock, A. Hultgren, and H. le Chatelier and B. Bogitch. H. le Chatelier and J. Lemoine used a similar soln., but with hydrochloric acid, 20 c.c., and water, 180 c.c. P. Oberhoffer used $CuCl_2$, 1·0 grm. ; $FeCl_3$, 20 grms. ; $SnCl_2$, 0·5 grm. ; hydrochloric acid, 50 c.c. ; water, 500 c.c. ; ethyl alcohol, 500 c.c. J. H. S. Dickenson recommended $CuCl_2$, 3 grms. ; $FeCl_3$, 40 grms. ; hydrochloric acid, 40 c.c. ; and water, 500 c.c. W. Rosenhain and J. L. Haughton recommended $CuCl_2$, 10 grms. ; $FeCl_3$, 30 grms. ; $SnCl_2$, 0·5 grm. ; hydrochloric acid, 100 c.c. ; water, 1000 c.c. H. le Chatelier and E. L. Dupuy recommended $CuCl_2$, 1 grm. ; picric acid, 0·5 grm. ; ethyl alcohol, 100 c.c. ; water, 10 c.c. ; and conc. hydrochloric acid, 1·3 to 2·5 c.c. ; A. Fry, crystalline copper chloride, 5 grms. ; conc. hydrochloric acid, 40 c.c.; water, 30 c.c. ; and ethyl alcohol, 25 c.c. ; and B. Kalling, 5 grms. $CuCl_2$, and 100 c.c. each of hydrochloric acid, alcohol and water. J. H. Whiteley used a soln. of 0·04 grm. of cupric oxide in 6 c.c. of conc. nitric acid made up to 200 c.c. with methylated spirit for etching iron-phosphorus alloys. O. Hengstenberg and F. Bornefeld used for

nitrogenized steels a soln. of a gram of mercurous chloride in 20 c.c. of conc. hydrochloric acid, and 80 c.c. of alcohol followed by a soln. of 10 grms. of magnesium chloride and a gram of cupric chloride in 40 c.c. of conc. hydrochloric acid and 100 c.c. of alcohol. F. C. Thompson and E. Whitehead found a soln. of **potassium copper cyanide** of assistance in discriminating different forms of cementite. **Silver nitrate**—M. Künkele dissolved 5 grms. of gelatin in 20 c.c. of water, then added 20 c.c. of glycerol, and 2 c.c. of sulphuric acid, and finally 0·8 grm. of silver nitrate dissolved in water. The liquid was used for sulphur inclusions. **Chromic acid**—G. d'Huart used a soln. of 40 grms. chromic acid ; 16 grms. NiCl$_2$; distilled water, 100 c.c. ; and conc. hydrochloric acid, 100 c.c. for mild steels, cast irons, and copper alloys. The soln. does not keep. **Ferric chloride** in acid— say 10 per cent. soln.—was recommended by H. le Chatelier, W. Ast, C. Frémont, N. Parravano, and A. M. Portevin ; L. Baraduc-Müller used a soln. of 100 c.c. nitric acid, 150 c.c. hydrochloric acid, and 500 c.c. of a soln. of ferric chloride. A. Hultgren used 100 grms. FeCl$_3$; 5 c.c. of conc. hydrochloric acid, and 250 c.c. each of water and alcohol ; and P. Oberhoffer, and K. Harneker and E. Rassow used distilled water, 500 c.c. ; ethyl alcohol, 500 c.c. ; stannous chloride, 0·5 grm. ; cupric chloride, 1·0 grm. ; ferric chloride, 30 grms. ; and conc. hydrochloric acid, 50 c.c. **Molten zinc**—J. L. Jones recommended immersing the specimen in molten zinc and afterwards removing the zinc or dross mechanically, or by dil. sulphuric acid.

The etching may be done electrically—**electrolytic etching**—by making the specimen the anode with a feeble current ; the cathode is a strip of platinum or a platinum dish ; and E. Heyn and A. Martens used 1 c.c. of hydrochloric acid in 500 c.c. of water as electrolyte. The subject was discussed by A. H. Sirks, and V. Velguth, W. Rosenhain and J. L. Haughton developed a *deposition method* in which the specimen is placed in a soln. of 30 grms. ferric chloride ; 100 c.c. of conc. hydrochloric acid ; one gram of cupric chloride ; 0·5 grm. of stannous chloride ; and a litre of water. The thickness and coloration of the copper films produced vary with the different constituents.

§ 14. The Equilibrium Diagram of the Iron-Carbon System

W. C. Roberts-Austen[1] showed that in addition to the Ar_3- and Ar_2-arrests with purified iron, two evolutions of heat occur at 487° and at 261°. These two points were observed with iron which had been heated in vacuo at 1300° for three successive periods. After repeated treatment, however, the two points become so feeble that they cannot be identified with certainty. Hence it is inferred that they are connected with the presence of hydrogen in iron. It was also observed that the presence of hydrogen increased the magnitude of the Ar_2- and Ar_3-arrests. The A_4-point at 1401° was found by R. Ruer and R. Klesper to be gradually lowered by silicon until it attained 1335° with 1·2 per cent. ; the addition of up to 0·29 per cent. of carbon raised it to 1482° ; likewise with up to 22 per cent. of cobalt it was raised to 1492° ; and with 11 per cent. of copper, to 1477°. H. W. Gillett discussed the action of oxygen and nitrogen on the iron-carbon system ; and F. Yamada, the effect of chemical composition on the liquidus curve of cast iron.

Carbon readily dissolves in γ-ferrite ; it is slightly soluble in β-ferrite ; and almost insoluble in α-ferrite. F. Osmond showed that if iron contains even a small proportion of carbon, an entirely new critical point occurs at approximately 690° or 710° on the cooling curve. This is called the Ar_1-arrest. It is inferred that the carbon is held in solid soln. by the iron at a temp. above the Ar_1-arrest, but at that temp. the carbon separates from solid soln. in the form of iron tritacarbide, Fe_3C, the so-called *cementite*, and the arrest is sometimes called the temp. of the carbide transformation. F. Osmond also observed that as

FIG. 82.—The Influence of Carbon on the Critical Points of Iron.

the proportion of carbon increases, the Ar_3-arrest is rapidly lowered and joins up with the Ar_2-point at a, Fig. 82 ; the double $Ar_{2,3}$-point then descends and finally coincides with the Ar_1-point, at E, when the proportion of carbon has attained 0·8 to 0·9 per cent. Such steels have one arrest, Ar_1, and it is sometimes called the $Ar_{3,2,1}$-point. The fact may be expressed other ways : Carbon retards the transformation of hard γ-iron into soft α-iron, and therefore increases the stability of hard γ-iron. The abrupt cooling or quenching of the iron-carbon alloy may result in hard γ-iron persisting at ordinary temp. when the transformation of γ- to α-iron is indefinitely slow. Alloying the iron with, say, manganese, nickel, chromium, tungsten, etc., considerably lowers the temp. of the Ar_1-arrest, so that the hard γ-iron may persist when the iron is cooled in air down to ordinary temp.—*vide infra*, air-hardening or self-hardening steels, and high-speed or rapid-cutting steels. F. Osmond found that the effect of foreign elements on the critical temp. when ranged in the order of their at. vols. is as follows : C, 3·6 ; B, 4·1 ; Ni, 6·7 ; Mn, 6·9 ; and Cu, 7·1. These elements with a smaller at. vol. than that of iron, *viz.* 7·2, delay the $\beta \rightarrow \alpha$ change as well as that of hardening carbon into carbide carbon. On the other hand, elements with a larger at. vol. than that of iron—*viz.* Cr, 7·7 ; W, 9·6 ; Si, 11·2 ; As, 13·2 ; P, 13·5 ; and S, 15·7—either raise or else maintain the $\beta \rightarrow \alpha$ change normal, and usually hasten the change of hardening carbon into carbide carbon. The subject was discussed by A. Sauveur, H. le Chatelier, K. W. Zimmerschied, A. Stansfield, H. M. Howe and co-workers, and G. K. Burgess and co-workers.

The work of K. Honda, K. Honda and H. Takagi, I. Iitaka, and T. Ishiwara showed that the A_2-point falls slightly at first with increasing proportions of carbon. It is also inferred that the A_2-point does not represent a change of phase, and that β-iron does not exist. The line ES represents the solubility of cementite, Fe_3C, in the solid soln. of austenite. The portion of the A_2abd line for the A_2-arrest represented by bd corresponds with austenite of concentration b, which changes from a weakly magnetic to a paramagnetic substance ; in the portion ab the concentration of the austenite changes from a to b, but no variation of the A_2-arrest occurs ; hence, steels with a concentration between A_2 and a'

consist of a mixture of ferrite and austenite of concentration a'. It is therefore inferred that the $A_s a$-line consists of two horizontal lines about 20° apart. As pure ferrite is approached, its quantity increases at the expense of the austenite ; on the other hand, as the austenite is approached, the quantity of austenite increases while that of ferrite decreases.

According to A. Grabe, and C. Benedicks, the A_1-critical point was first noted in Sweden by A. F. Angerstein, in 1777, in a paper afterwards discussed by S. Rinman. A. F. Angerstein said that when steel is heated, there is " a kind of twinkling, or, so to speak, a fluttering, flitting like a fog or vague shadow on the glowing steel " ; and this is taken to mean that on heating a piece of steel a slight cooling sets in at a definite temp., which was considered to indicate the right moment for quenching to produce the best hardening effect, and the finest grain. It was not until nearly a century later that D. K. Tschernoff noticed the connection between the critical point and the hardening of steel. This was followed by the work of F. Osmond just indicated.

Observations on the allotropic forms of iron have been largely concerned with iron associated with small proportions of other elements which inhibit or retard their transformation during cooling into the form or forms normally stable at ordinary temp. Most observations have been made with iron associated with carbon ; and the forms stable at higher temp. have been cooled or quenched before the metal has had time to pass into a state of equilibrium. At the lower temp. the speed of transformation into the state of equilibrium is often indefinitely slow. In some cases the presence of another element may reduce the transition temp. so that a state which is stable, in its absence, only at a high temp., is stable at a low temp. when it is present. For the doubling and tripling of the Ar_1-arrest, *vide infra*. A. Hultgren, G. W. Sargent, P. Goerens and H. Meyer, G. Goldberg, J. O. Arnold, J. E. Storey, A. Sauveur, and J. H. Andrew and H. A. Dickie studied the A_1- and the other transformations.

The work on the iron carbides—**5**. 39, 20—shows that in all probability molten carburized iron is a soln. of carbon or of iron tritacarbide in iron. The solidified mass is a solid soln. or a mixture of solid soln. with or without iron, *i.e.* **ferrite ;** and iron tritacarbide, *i.e.* **cementite.** In 1806 J. L. Proust in his paper *Fonte de fer* regarded carburized iron or steel as a solidified soln. of carburetted cast iron in an excess of iron ; and he added that this is but one example of a multitude of cases of solution of a compound by one or other of its elements, or even by other compounds. In 1863 A. Matthiessen suggested that the metal alloys can be regarded as solutions of metals or metal compounds in one another. The application of the laws of dil. soln. to the molten carburized iron was made by B. Pawlewsky, W. Campbell, J. A. Mathews, A. Stansfield, E. Heyn, E. D. Campbell, T. T. Read, J. H. Stansbie, G. Quincke, A. M. Portevin, C. A. Edwards, E. Nusbaumer, F. Rosendahl, G. J. Snelus, J. Parry, and H. von Jüptner ; and the phase rule, by H. W. B. Roozeboom, H. le Chatelier, O. E. Harder and F. Gonzalez, T. K. Rose, E. L. Dupuy, Z. Jeffries, Z. Jeffries and R. S. Archer, F. Osmond, N. T. Belaiew, L. Grenet, C. A. Edwards, C. Benedicks, E. Frasenster, W. Broniewsky, W. Rosenhain, A. Linder, F. T. Sisco, and F. J. Brislee. N. H. Aall studied the diagrams for the binary and ternary systems ; and T. F. Russell, P. Oberhoffer and co-workers, R. Vogel, K. Fishbeck, P. Goerens, and A. von Vegesack, the use of triangular and space diagrams for representing the equilibrium conditions of ternary iron-carbon alloys. F. Wever, Y. Chu-Phay, and F. H. Jeffery discussed the thermodynamics of the transformations.

In 1879 R. Mannesmann represented some relations between carbon and iron by means of a diagram ; and a few years later W. C. Roberts-Austen depicted the thermal transformations of the iron-carbon system in one diagram. This was improved by H. W. B. Roozeboom, and made to include data obtained by F. Osmond. Even then the relations were admittedly tentative. The diagram is illustrated by Fig. 83 and the dots represent the thermal data obtained by H. C. H. Carpenter

and B. F. E. Keeling.   The observed results represented by dots in Fig. 83 confirm
H. W. B. Roozeboom's diagram ; but AC is slightly convex upwards ; EC rises
slightly from E to C ; SE can be represented as well by a straight line as by a

FIG. 83.—Equilibrium Diagram of the
Iron-Carbon Alloys.

curve ; and PK rises in passing from P to K.
In addition, (i) a small thermal change
occurred at about 790° for alloys with 0·8 to
4·5 per cent. carbon ; (ii) a slow thermal
change occurred at about 600° with all the
alloys ; and (iii) evolutions of heat at about
900° occurred in two of the alloys.   The
liquidus curve, AC, Fig. 83, shows how the
f.p. is influenced by the amount of carbon
present, there being a continuous drop from
the m.p. of iron, 1505°, to 1130°, the eutectic
temp. for a mixture with about 4·3 per cent.
carbon.   The solidus line Aa represents temp.
below which the whole mass is solid.
N. Gutowsky found that the solidus line Aa
for mixtures with less than 2 per cent. carbon
is convex downwards as indicated in Fig. 83 ;
and G. Asahara obtained for the solidus a position intermediate between the
curves of N. Gutowsky, and H. C. H. Carpenter and B. F. E. Keeling.   The
liquidus and solidus curves were discussed by O. W. Ellis.   The solid which separates
from the cooling liquid along AC is a solid soln. to which the name **austenite** has
been applied—after W. C. Roberts-Austen.   Solid alloys with less than 2 per cent.
of carbon contain iron carbide held in solid soln. by γ-iron.   The alloys with up to
2 per cent. carbon persist as a homogeneous soln. of tritacarbide in γ-iron down to
temp. denoted by the lines $GOSE$.   The mixture represented by the point S—0·9
per cent. carbon—is called the *eutectoid* or eutectic steel ; mixtures with a smaller
proportion of carbon are called *hypoeutectoids*, and mixtures with 0·9 to 2·0 per cent.
carbon, *hypereutectoids*.

H. M. Howe considered that the term eutectic steel may lead to confusion, and pro-
posed the term *bonmutic steel* for the steel with the lowest transformation temp., but later
preferred *œolic steel*.   The term has not been adopted.   The subject was discussed by
B. H. Brough, A. Sauveur, J. O. Arnold, and A. Stansfield.

The hypoeutectoidal mixtures to the left of S, on passing the temp. represented
by GO, yield β-iron, and on passing the temp. represented by OS, α-iron.   On
reaching the temp. represented by PS, the Ar_1-arrest, the remaining alloy is eutec-
toidal and it passes into a mixture of α-ferrite and cementite.   During the cooling
of the hypereutectoidal alloys, with between 0·9 and 2·0 per cent. of carbon, to the
right of S, the curve SE is reached ; this represents the limit of saturation of the
solid soln. of tritacarbide or cementite in γ-iron, so that as the temp. falls, the
austenite is resolved along the line ES into γ-iron and cementite, until the eutectoidal
mixture is attained.   J. H. Andrew and D. Binnie found that the liquidus and
solidus curves of commercial carbon steels conform with Fig. 84, provided the pro-
portion of manganese is below 0·45 per cent.   K. Honda and H. Endo found that
the solidus line lies between that of H. C. H. Carpenter and B. F. E. Keeling, and
N. Gutowsky, and nearly coincides with that obtained by G. Asahara, and by
S. Kaya.   O. W. Ellis discussed the solidus curve ; and G. Gesaro, the liquidus
curve.

The line GOS thus represents the effect of carbon on the critical temp. of iron.
With about 0·45 per cent. of carbon the Ar_3-arrest is practically coincident with
the Ar_2-arrest ; and with 0·9 per cent. of carbon the Ar_3-, Ar_2-, and Ar_1-arrests
coincide.   The line PSK represents the temp. at which the solid soln. of carbide
separates into cementite and α-ferrite.   The eutectoidal mixture has 0·9 per cent.
of carbon.   The eutectoidal mixture, roughly six parts of ferrite to one of cementite,

is called **pearlite,** owing to the fact that it can be made to show the rainbow tints of mother-of-pearl. The eutectoidal line *PSK* was found by H. C. H. Carpenter and B. F. E. Keeling to have a slight upward slope beyond the eutectoidal point *S* ; but it is usually drawn horizontal, because, in the observation of eritical temp. on cooling curves, the observed results may be affected by under-cooling. Obser- vations on the transformations associated with the zone *GOSP*, Fig. 83, have been considered in connection with the allotropic forms of iron ; and in addition, by R. Ruer and F. Goerens, P. Bardenheuer, H. M. Howe, P. Goerens and P. Saldau, M. Levin and H. Schottsky, O. F. Hudson, W. J. Foster, H. Hanemann, R. Ruer and co-workers, W. H. Hatfield, A. Meuthen, J. Driesen, G. Rümelin and R. Maire, P. Curie, A. Merz, F. Stahlein, H. Esser, and S. Hilpert.

In constructing his equilibrium diagram, H. W. B. Roozeboom assumed that graphite forms the more stable system at the higher temp., and this view was favoured by A. Stansfield, and H. Le Chatelier, and E. Heyn. This means that the equilibrium diagram includes two systems—a metastable system free from graphite, and a stable system free from carbide. The metastable carbide system is supposed to be in a state of undercooling. E. Heyn added that if the proportion of carbon exceeds a certain limiting value, undercooling is prevented, and that occluded gases may favour the transformation of the metastable into the stable system. G. Charpy inferred that the system produced depends on the rate of cooling during solidification, and he assumed, but did not prove, that the graphite-iron eutectic is 10° to 15° above the carbide-iron eutectic.

F. Osmond inferred from his observations on the quenching of grey cast iron that the graphite is produced in the solidified metal. F. Wüst obtained only one eutectic for both systems ; he regarded this as the carbide-iron eutectic ; and inferred that graphite is not a primary product at all, but rather a secondary product being produced by the decomposition of the carbide—the yield of graphite being greater the longer the alloy is maintained in the region of solidification. E. Heyn and O. Bauer found that some alloys with silicon can be solidified without the separation of graphite, and that the graphite is formed in the solidified metal within 30° or 40° below the m.p. Quite a number of observers agreed that graphite is not a direct product of the freezing of the iron-carbon alloy, but is rather formed by the decomposition of the carbide, cementite=graphite+pearlite, soon after its solidifica- tion from the molten state. A similar view of the process of graphite formation was taken by P. Goerens, P. Goerens and N. Gutowsky, A. M. Portevin, J. E. Stead, K. Honda and T. Murakami, K. Honda and H. Endo, L. Northcott, M. Hamasumi, and J. E. Hurst. E. Mauer and P. Holtzhaussen, and E. Schüz concluded that only the eutectic graphite is formed by direct separation from the alloy, but that the other graphite is produced by the secondary decomposition of the carbide.

On the other hand, C. Benedicks argued that graphite can separate directly from the freezing liquid, and this view was supposed by H. M. Howe, H. Hanemann, W. Guertler, J. E. Johnson, R. Ruer and F. Goerens, O. Ruff and W. Bormann, K. Tawara and G. Asahara, P. Bardenheuer, A. Logan, K. von Kerpeley, and D. Hanson. The eutectic for the iron-carbon alloys occurs with 4·3 per cent. carbon ; alloys with 2 to 4·3 per cent. carbon are said to be *hypoeutectic,* and those with over 4·3 per cent. carbon, *hypereutectic.* The hypereutectic alloys deposit cementite as cooling occurs along the line *CD.* The eutectic line *ECF* corresponds with the formation of the eutectic mixture of cementite and austenite. The iron carbide in solid soln. under certain conditions may decompose into iron and graphite or free carbon—at first probably colloidal. Iron containing 4 per cent. of carbon in soln., if rapidly cooled from the liquid state, will contain all the carbon in solid soln. probably as carbide, but when slowly cooled most of the carbon will separate free. In 1881 L. Forquignon showed that hard carbides may be decomposed when the metal is annealed—*vide infra,* cast iron. The carbide present in rapidly cooled iron can be decomposed at about 1000°. Free carbon can be readily produced by annealing steels with over 9·0 per cent. carbon, and in steels with a lower percentage

by a prolonged annealing just below 700°. This means that there are two equilibrium diagrams for the iron-carbide alloys, either a metastable diagram in which the carbide in solid soln. does not decompose into free carbon, etc., or a stable diagram in which the carbide is decomposed, or conversely. There are workers who believe that for true equilibrium no carbide will be present, and that iron carbides have no place in the true equilibrium diagram. E. Heyn, R. Ruer, and C. Benedicks suggested diagrams in which the graphite is represented as one of the constituents to separate from the eutectic if the cooling be slow enough, and if the cooling be fast enough iron carbide and not graphite is produced. According to K. Honda and H. Endo, if graphite be a decomposition product of cementite, and not a direct precipitation product from the solid soln., the double diagram is not a correct representation of the facts. C', Fig. 84, represents the *graphite eutectic*; and C, the *cementite eutectic*. F. Wüst called the eutectic mixture of austenite and cementite
FIG. 84.—Stable and Metastable Equilibria Curves of the Iron-Carbon Alloys.
FIG. 85.—Equilibrium Diagram of the Iron-Carbon Alloys.

ledeburite—after A. Ledebur; and H. A. Schwartz and co-workers, solid soln. of iron and graphite **boydenite**—after S. Boyden—so that the term boydenite is used for a solid soln. of carbon in γ-iron in the same sense that austenite is used for a solid soln. of cementite in γ-iron—but *vide infra*. K. Daeves discussed the eutectic points in the iron-carbon system. According to R. Ruer and J. Biren, the eutectic with graphite is 1152° and 4·25 per cent. of carbon, but with cementite it is 1145° and 4·30 per cent. of carbon. Graphite can separate from molten hypereutectic alloys, and rising to the surface produce the so-called **kish.** Graphite or kish may thus be formed in the region $C'D'F'$, as cementite is formed in the region CDF. As shown by B. Osann, graphite is also formed in the slow cooling of iron-carbon below $E'C'D'$; and graphite or annealing carbon is formed after the prolonged annealing of other iron-carbon alloys, and it separates by the decomposition of austenite as the alloy is cooled through temp. represented by the line $S'E'$, just as under other conditions cementite separates along the line SE.

These conclusions on the transformation of combined carbon into graphite have been discussed by R. R. Abbott, P. Goerens, P. Goerens and N. Gutowsky, A. Hague and T. Turner, E. Adamson, J. Shaw, W. J. Foster, G. Phragmen, A. Merz and F. Fleischer, R. Ruer, K. Honda, A. A. Bates and co-workers, R. L. Dowdell, J. H. Andrew, A. Ledebur and G. Charpy, W. H. Hatfield, H. M. Howe, F. Wüst, F. Wüst and P. Schlösser, H. Hanemann, O. Ruff, O. Ruff and O. Goecke, N. M. von Wittorf, A. Smits, B. Osann, R. Horny, W. Guertler, E. H. Saniter, H. A. Schwartz and co-workers, P. D. Merica and L. J. Gurevich, R. S. Archer, A. E. White and R. S. Archer, A. Phillips and E. S. Davenport, R. W. Bean and co-workers, K. Tawara and G. Asahara, and G. Charpy and L. Grenet—*vide infra*, the graphitization of cast iron.

O. E. Harder and W. S. Johnson examined normal and abnormal steels respectively with 0·012 per cent. C; 0·021, Mn; 0·005, P; 0·038, S; 0·054, Cu;

and with 0·20, C; 0·43, Mn; 0·022, P; 0·033, S, and found that the cementite solubility curve with normal steel is shifted to the left, so that the eutectoid comes at 0·75 per cent. carbon instead of 0·9 per cent. Similarly with abnormal steel, which is shifted still further to the left so as to cut the A₁-line at about 0·55 per cent. of carbon. N. J. Wark, L. Grenet, and E. Walldow studied the dissolution of cementite in α- and γ-iron ; and J. O. Arnold and L. Aitchison, the solubility of cementite in hardenite —*vide infra*. O. E. Harder and co-workers also represented in Fig. 84 the results when iron oxide and alumina are present.

Fig. 86.—The Solubility of Carbide in Normal and Abnormal Steels.

Fig. 87.—The Solubility of Carbide in Steels with Iron Oxide and Alumina.

The results of R. Ruer and F. Goeren's, and of K. Honda's observations on δ-iron are included in the diagram. It also includes diagrammatically D. Hanson's assumptions based on his observations on the Fe–Si–C-system that the SE and $S'E'$ lines intersect so that graphite is the stable form at the higher temp., and carbide at the lower. It also shows how graphite can be the stable form for all alloys with over about 2 per cent. of carbon (and 0·4 per cent. of silicon—*q.v.*) ; and carbide is the stable form in steels. Intermediate zones are assumed to exist in which both forms have the appearance of being stable under ordinary conditions. Observations on this part of the equilibrium diagram were also made by G. Z. Nesselstrauss, K. Daeves, O. Ruff, O. Ruff and O. Goecke, O. Ruff and W. Bormann, I. Iitaka, L. Persoz, A. A. Bates and co-workers, S. Epstein, H. Hanemann, H. M. Howe, and R. B. Fehr. All these possibilities show how very imperfect is our knowledge of the equilibrium diagram of the iron-carbon system ; and this in spite of the extraordinary amount of work which has been done on the subject.

The line $S'E'$, Fig. 85, for the " graphite separation " does not necessarily mean that graphite as such is formed, since the separation may be temper carbon or annealing carbon and what has been called agraphitic carbon. H. A. Schwartz and co-workers said that they conceived the so-called graphitization to occur somewhat as follows :

At fairly high constant temp., say 900° to 1000°, the process is initiated by the separation of a graphite nucleus, possibly due to carbon precipitated out by some local conversion of austenite into boydenite and excess carbon. The bulk of the solid soln., however, remains austenitic and maintains its carbon conc. by dissolving cementite. More carbon precipitates and more cementite dissolves until the latter is used up, when there remains a matrix of austenite and grains of free carbon. This reaction is relatively rapid. Subsequently the austenite is graphitized into boydenite and free carbon, and reaction ceases when the solid soln. is boydenite of a carbon conc. corresponding to the saturation point at the temp. chosen. If the temp. falls slowly enough, carbon precipitates along the $S'E'$ line, the boydenite decreases in carbon content. Just above the Ar₁-arrest the solubility of carbon in boydenite is about 0·50. The agraphitic carbon becomes almost nil below Ar₁-stable and ferrite is formed, the remaining carbon precipitating as ferrite-carbon eutectoid. As a matter of fact, carbon is probably soluble in ferrite, so that the carbon concentration at the Ar₁-arrest has a small finite value ; in this case it was less than 0·03 per cent. If the temp. falls too rapidly to permit the boydenite to decrease its carbon content by precipitation, austenite will be formed, the metastable mix crystals having a higher carbon conc. than the stable. If the temp. falls somewhat rapidly below the Ac₁-arrest, metastable pearlite may form and graphitization will still proceed, though very slowly because of the slight carbon solubility at that temp. The ferrite ring around the temper carbon under these conditions, which is really a ring of boydenite of extremely low carbon content, suggests the rapid migration of carbon when dissolved as such. There is no evidence of the existence of the S'-eutectoid, and there may be a sharp inflection in the $E'S'$-curve so that it bends over to zero carbon at the A₁-arrest.
The relative portions of the $S'E'$ and SE-lines have not been precisely determined. In C. Benedicks', and N. M. von Wittorf's diagrams, these curves agree with the assumption that with slow cooling the iron carbide in soln. should break down into iron and carbon, since the carbon solubility line lies wholly to the left of the cementite solubility line. On the other hand, on O. Ruff's diagram, the curve $S'E'$ approaches and possibly intersects SE before the $A_{2,3}$- or the A_3-arrest is reached. $E'S'$ intersects ES at a point Q; this would mean that graphite is the stable phase at the higher temp., above the point of intersection, and cementite, at the lower temp., below Q. Analogous diagrams can be constructed to show the carbide stable at the higher temp., and graphite at the lower temp. These possibilities were discussed by D. Hanson, Fig. 88. Whether the alloy graphitized or not then depends on whether $S'E'$ intersects the A_3- or $A_{3,2}$-lines on the one hand or the SE-line on the
FIG. 88.—Constitutional Diagram of Carbon-Iron Alloys with no Silicon.

other hand. In the former case α-iron, carbon, and solid soln., sat. with carbon, would be in equilibrium, and the extraction of heat at the temp. of intersection should make the solid soln. break down into α-iron and carbon. If the $S'E'$-line intersects the SE-line, carbon, cementite, and solid soln., sat. with carbon, would be in equilibrium, and the extraction of heat would produce cementite from carbon and solid soln. The relative slopes of the $S'E'$ and SE lines, near 700°, are determined by the relative values of the heats of soln. of carbon and cementite in the sat. solid soln. if the difference between the solubilities of carbon from carbon and from cementite is not great. If the formation of cementite is accompanied by the evolution of much heat, the slope of the $S'E'$-line will be less than that of the SE-line, as in C. Benedicks' diagram, and if the formation of cementite is attended by the absorption of much heat, the line $S'E'$ will have the greater slope, as in O. Ruff's diagram. These considerations led H. L. Maxwell and A. Hayes to determine the heats of formation and free energy of cementite between 650° and 700°. It was found that for 3α–$Fe+C$ graphite$=Fe_3C$ the heats of formation at 650° and 700° are respectively $+3138$ cals. and 2281 cals., and the free energies 19,163 cals. Determinations of the course of the cementite line, SE, have been made by W. C. Roberts-Austen, E. Heyn, H. C. H. Carpenter and B. F. E. Keeling, N. J. Wark, P. Goerens and P. Saldau, S. Epstein, N. Gutowsky, N. Tschieschewsky and N. Schulgin, and H. M. Howe and A. S. Levy.

A. L. Norbury has studied the constitutional diagram for cast irons and steels, and observed that in one type of iron the graphite may occur in a finely-divided form which has been called *supercooled graphite*; and in the other type of iron the graphite, occurring in relatively coarse flakes, has been called *normal graphite*. All intermediate stages between these two types have been prepared. When the silicon content is below 3 per cent., there is a tendency for the fine graphite to associate with ferrite in the matrix. The fine, supercooled graphite has been obtained by E. Piwowarsky, H. Hanemann, and P. Bardenheuer and K. L. Zeyen by superheating the melt; and they assume that the refining of the grain-size of graphite is due to the destruction of graphite nuclei in the melt. E. Schüz obtained the fine form of graphite by casting "iron" with 3·5 per cent. silicon in chill-moulds; and C. Irresberger, by jolting molten cast iron which had been melted with additions of steel. The fine graphite structure has frequently been reported—*e.g.* by

A. Hague and T. Turner, and H. I. Coe. A. L. Norbury represented the phase boundaries of iron-carbon alloys with 0, 2, and 4 per cent. silicon by Figs. 88 to 90. These diagrams show both the austenite-cementite and austenite-graphite for normal and supercooled systems. A. L. Norbury said that the grey irons have been assumed to crystallize according to the normal graphite-austenite system when graphite nuclei are present in the melt. Such irons contain coarse graphite flakes and tend to be pearlitic. Conversely, when graphite nuclei are absent, supercooling occurs, and the graphite is deposited in the form of exceedingly fine flakes which tend to be associated with ferrite. In the case of white iron it has been assumed that nuclei cause the precipitation of small amounts of graphite eutectic, which in turn cause the precipitation of white iron eutectic at the maximum possible temperature and with consequent coalescence. In grey irons the tendency for coarse graphite to be associated with pearlite, and fine graphite with ferrite, has been explained by assuming that the γ-solid soln. adjacent to the graphite flakes holds carbon in solid soln. according to the (lower) solid solubility of graphite, while that away from the graphite flakes holds carbon in solid soln. according to the (higher) solid solubility of cementite. Consequently, the coarser and the fewer the graphite flakes, the higher the percentage of carbon in solid soln. The lowering of the change points in steels
FIG. 89.—Constitutional Diagram of Carbon-Iron Alloys with 2 per cent. of Silicon.

FIG. 90.—Constitutional Diagram of Carbon-Iron Alloys with 4 per cent. of Silicon.

due to quenching has also been represented in a constitutional diagram as a form of supercooling. In the three diagrams the positions assigned to them are only approximately correct. $E'C'$ represents the eutectic temp. for normal graphite, and $(E')(C')$ the eutectic line for supercooled graphite. The work of F. Wüst and O. Petersen, and A. Hague and T. Turner indicates that the one line is about 20° higher than the other. The results of W. Gontermann, D. Hanson, and K. Honda and T. Murakami refer to intermediate temp. Similarly for the normal cementite eutectic EC, at 1110° in Fig. 88, at 1105° in Fig. 89, and at 1100° in Fig. 90, the coarse graphite eutectic is placed at 4·3, 3·75, and 3·25 per cent. carbon respectively for 0, 2, and 4 per cent. silicon alloys. The liquidus lines joining the four eutectics are shown in the diagram, and similarly with the solidus lines. The solubility curves for graphite are represented by $(S')(E')$, and for cementite by SE. The curves involving the $\delta=\gamma=\alpha$-allotropic changes are based on the observations of R. Ruer and R. Klesper, F. Wever and P. Giani, and A. Sanfourche. The suppression of the γ-phase with high proportions of silicon was demonstrated by F. Wever and P. Giani and predicted by P. Oberhoffer. K. Tamaru supposed that the solid solubility curve of carbon in δ-iron is a continuation at high temp. of the solubility curve of carbon in α-iron. The lowering of the temp. of magnetic change, M, from 768° was demonstrated by the work of T. Baker, E. Gumlich, F. Wever

and P. Giani, and K. Honda and T. Murakami.   E. Scheil did not agree with D. Hanson that the double diagram is at variance with the phase rule.   C. P. Yap studied the thermodynamics of the system.

The effect of pressure on the iron-carbon equilibrium diagram has not been closely studied.   G. Tammann's results for the effect of variations of pressure show that the A_2-arrest remains constant, whilst the A_3-arrest is lowered by pressure. Hence there are indications of a triple point.   G. Charpy observed that the separation of graphite is favoured by press.   When a white cast iron, containing 3 per cent. carbon and 4 per cent. nickel, or one containing 3 per cent. carbon and 2 per cent. nickel, is heated at 1100° under a press. of 150 kgrms. per sq. mm. until no further decrease in vol. occurs, graphite occurs in the cold product.   The longer the heating, the greater the proportion of graphite formed.   Similar results were obtained with cementite.   The quantitative estimate of E. Scheil and E. H. Schulz is summarized in Fig. 91.   C. Benedicks inferred that mechanical stress may cause a partial conversion of γ- into α-iron.
FIG. 91.—The Effect of Variation of Pressure on the Critical Points.
FIG. 92.—The Effect of Pressure and Temperature on the Iron-Carbon System (Diagrammatic).

O. Ruff and O. Goecke studied the relations between iron and carbon at higher temp. and higher concentrations than those now under consideration; for this, *vide* 5. 39, 20 (Fig. 31).   R. Ruer and J. Biren found that the solubility curve of graphite in molten iron is almost linear between 1152° and 1700°, and after that is slightly concave towards the concentration axis.   The data for the percentage solubility, S, are :

	1152°	1200°	1400°	1600°	1800°	2000°	2200°	2400°	2500°
S .	4·25	4·37	4·85	5·37	6·00	6·78	7·72	8·88	9·54

H. A. Schwartz and co-workers suggested that the solid soln. of graphite—called boydenite—is not the same as the so-called metastable solid soln. of carbide—called ledeburite ; and they concluded that the presence of some silicon is necessary for the existence of the boydenite.   This is another way of saying that the graphitic solid soln. is less stable than the carbide solid soln. E. Schüz observed that a structure having the appearance of the graphite eutectic can be observed in cast iron only when it contains a high proportion of silicon and when it has been rapidly chilled from the molten state.   The alleged graphite eutectic consists of a mass of finely divided plates of graphite evenly dispersed in a ground-mass of austenite, or its derived products.   J. E. Hurst observed that when a sample of hypoeutectic pig-iron was melted and allowed to cool in air, the part which cooled slowest had finely-divided graphite plates evenly dispersed in a matrix of ferrite and pearlite.   Another

sample showed a mass of dendrites of austenite free from graphite, with graphite in the intermediate spaces, and this part had all the appearance of a eutectic— Fig. 93 ($\times$75). Of course, the mere fact that a structure has the appearance of a eutectic is not a sufficient proof that the structure is really eutectic, when it has not been shown that the alleged eutectic is produced at a definite temp., and that it has a constant composition. The fact that the final solidification of these alloys furnishes the austenite-cementite eutectic is assumed to be due to undercooling. The phenomenon occurs, however, even when the alloy is seeded with graphite—e.g. (i) when samples are melted while surrounded by graphite, and (ii) when hypereutectic alloys which liberate graphite still give as a result of the supposed undercooling the austenite-cementite eutectic. The supposed graphite eutectic structure can be produced by annealing at 1050°, when the structure is not eutectic because it has been produced below the final solidification temp. Hence, E. Schulz admitted that it has not been possible to find why the solidification of molten iron in adjacent parts should proceed at one time so as to furnish the graphite system, and at another time, the cementite system ; and still less so why the white and

FIG. 93.—Hypoeutectic Iron with the Appearance of a Graphite Eutectic mixed with Dendrites of Austenite (J. E. Hurst).

grey patches are formed not regularly on the outside or in the middle of the drops, but quite irregularly throughout the mass. The general conclusion is that carbon exists in the molten alloy as carbide, and that the available evidence does not favour the assumption of a graphite-austenite eutectic. W. H. Hatfield, H. le Chatelier, A. Baykoff, and A. I. Krynitsky have discussed this subject.

According to J. E. Hurst, the possibility of obtaining the alleged graphite structure by the heat treatment of the solid, and the fact that quenching the alloy containing graphite from the vicinity of its final solidification temp. furnishes the austenite-cementite eutectic, make it probable that the carbon is dissolved as carbide in liquid iron, and that the existence of an austenite-cementite eutectic is not proven. The alleged graphitic eutectic is a kind of transitional stage in the appearance of the separated graphite and is formed within certain limiting conditions of cooling and composition. The formation of the austenite-cementite structure with no free carbon during the rapid quenching of the molten alloys from all temp. down to the final solidification temp., is taken to mean that the cementite is the stable phase down to temp. slightly below the final solidification temp., and is not necessarily a result of undercooling. The subsequent appearance of graphite is attributed to the breaking down of the austenite or austenite-cementite structures at lower temp. The production of kish in the liquid hypereutectic is attributed to the presence of silicon or of some other impurity—a subject discussed by W. H. Hatfield, and J. E. Stead. It is assumed by W. Gontermann, J. E. Stead, J. H. Andrew, and C. A. Edwards that with the hypoeutectic alloys it is primary austenite which separates from the cooling liquid, and with hypereutectic alloys, cementite ; the cementite is the stable phase down to temp. a little below the eutectic temp. According to J. E. Stead, when hypoeutectic alloys low in silicon solidify, nearly all the silicon separates out with the primary austenite, and by gradually increasing the carbon so as to reduce the quantity of primary austenite, the austenite is gradually enriched in silicon up to the point of saturation ; and when that point is reached, the excess silicon crystallizes out with a portion of the iron carbide to form an iron silicocarbide. In eutectic and hyper-

eutectic alloys no primary austenite can form, and the silicon crystallizes out with the carbide. The primary carbosilicides are very unstable, and they are the first to decompose into graphite and silicoaustenite. In the absence of all but traces of phosphorus, two cementites form and crystallize as a eutectic mixture—one is silicocarbide-cementite, and the other a carbide-cementite. The unstable silico-carbides are responsible for the greyness of commercial irons rich in silicon and low in sulphur. When white iron is heated to 1000° with iron silicide, it decomposes into graphite and iron. Hence the silicon of hypoeutectic alloys crystallizes out with the primary austenite; and after the carbide has solidified a diffusion of the silicide occurs, and this leads to the decomposition of the iron carbide into graphite and iron.

N. M. von Wittorf's diagram is shown in Fig. 94, where the assumption is made that different iron carbides are formed—*vide* 5. 39, 20. M denotes molten alloy; I, austenite (γ-iron); II, β-iron; III, α-iron; IV, graphite; V, Fe_4C; VI, Fe_3C or cementite; VII, FeC_2. It illustrates how very uncertain is the state of our knowledge of the details of the binary system: Fe–C. H. M. Howe, B. Stoughton, N. N. Ljubavin, G. Auchy, A. Smits, and O. Ruff discussed these different carbides—*vide* 5. 39, 20.
FIG. 94.—N. M. von Wittorf's Equilibrium Diagram of the Iron-Carbon Alloys.
FIG. 95.—Portion of Equilibrium Diagram of the Iron-Carbon System Associated with Small Proportions of Carbon.

C. A. Edwards explained the formation of kish by assuming an upper limit of stability of cementite-carbide as indicated by MN, Fig. 95, so that at temp. and conc. a little in excess of those of the eutectic alloy, the cementite-carbide is stable, and crystallizes from the molten metal. The break at M in the liquidus curve corresponds with the reaction $Fe_3C=Graphite+Melt$. No such break, however, was observed by O. Ruff and O. Goecke, and H. Hanemann in their studies of the hypereutectic alloys. G. B. Upton also made an attempt to deal with the formation of graphite by assuming the existence of a number of complex carbides. There is no definite arrest on the cooling curves corresponding with the separation of graphite, for the graphite may separate continuously over a considerable range of temp. below the solidification temp. of the eutectic. Several other modified equilibrium diagrams have been proposed—*e.g.* by G. B. Upton, A. Vinogradoff, etc.

J. H. Andrew said that the formation of graphite commences between 1150° and 1100°; K. Honda and T. Murakami, between 1150° and 1130°; and L. Northcott, between 1145° and 1000° with ordinary grey cast irons. The assumption that graphite begins to be formed at least 5° or 10° below the solidification temp. of the eutectic is in agreement with the observations of J. O. Arnold, C. A. Edwards, W. Gontermann, and G. Cesaro. Unlike R. Ruer and F. Goerens, K. Honda and

T. Murakami concluded that graphite is not directly precipitated from the molten soln. of iron and carbon, but is a secondary product of the decomposition of the solidified cementite. Consequently, the graphite system is not an integral part of the iron-carbon equilibrium diagram. The conclusion is based on these facts :

(i) If a specimen of cast iron is quenched from 1130°, when it has just solidified, no graphite is observable, provided the alloy is hypoeutectic ; while in specimens quenched between 1050° and 1000°, a considerable amount of graphite is found in the microstructure. Moreover, in specimens very slowly cooled through the solidifying range, the graphitization is very small. If the graphite were a direct product from the melt, it should be found in specimens which have just solidified and been quenched from 1130°, or slowly cooled through the solidifying range ; but this is not the case. (ii) If the graphite were a product directly precipitated from the melt, it must be found in a greater quantity round a graphite rod dipped in it, because a new phase easily appears when a nucleus of the same phase exists. But this conclusion is not confirmed by experiments. (iii) Flaky graphite, which is similar to that produced during cooling from the melt, is also obtained by heating solidified alloys containing cementite from 1000° to 1100°. This fact clearly shows that cementite can graphitize and form flakes at a temp. below the eutectic point. (iv) K. Honda and H. Endo found that the contraction which occurs when cast iron solidifies is 3·5 per cent., provided no cementite decomposes. If graphite be a decomposition product of cementite, the change in vol., $\delta v/v$, on solidification will be $\delta v/v = -3\cdot6+$ the vol. change due to the decomposition of the cementite. The observed and calculated results agree.

The general conclusion of O. Ruff and W. Bormann, R. Ruer and F. Goerens, G. Charpy, F. Wüst, K. Honda and co-workers, T. Kase, and H. Sawamura is that graphite is produced by the dissociation of the primarily formed carbide as it cools below the solidification of the austentite-cementite eutectic. It is simplest to suppose that the carbide dissociates $Fe_3C = 3Fe + C_{graphite}$. Assuming that cementite is the metastable phase, and graphite the stable phase, the formation of the metastable intermediate phase anterior to the appearance of the stable one is in general agreement with the observations of W. Ostwald on the transition of substances from one state to another. On the other hand, K. Honda suggested that graphite is formed by a strictly chemical process, namely the catalytic action of free carbon dioxide on the cementite : $Fe_3C + CO_2 = 2CO + 3Fe$; followed by $2CO = CO_2 + C_{graphite}$, and the resulting carbon dioxide maintains the continuity of the cycle. According to these hypotheses, free ferrite must occur along with the graphite, but this has not been observed. Hence it is assumed that the cementite-carbide dissociates into graphite and a solid soln. of carbon in iron ; $Fe_3C = C_{graphite} + $ solid soln. of carbon in iron. The solidification of a cooling soln. of carbide in molten iron furnishes a mixture of austenite and the austenite-cementite. This is stable down to about 1100°, when the primary cementite of the eutectic may furnish graphite and a solid soln. As the austenite cools down it becomes saturated with respect to carbide, and needles of secondary cementite are deposited. The line SE represents the solubility of cementite in the solid soln. The secondary cementite can presumably dissociate into graphite and solid soln. T. Kase's observations on the cooling curves, the microstructure of cast iron cooled under various conditions, and the change of electrical resistance near the eutectic temp. favour the interpretation that graphite is a secondary product. The two-stepped thermal change observed by R. Ruer and F. Goerens with the austenite-cementite and the austenite-graphite eutectics does not prove that graphite is a primary product ; T. Kase said that the phenomenon is due to the difference in the velocity of the mutual dissolution of cementite and austenite, and graphite and austenite, respectively. No evidence of the presence of two eutectic temp. could be observed ; for the two eutectic horizontals sometimes observed are attributed to the difference in the speed of melting of the austenite-cementite and austenite-graphite systems. The so-called eutectic graphite—boydenite—is a decomposition product of the eutectic cementite.

P. D. Merica and L. J. Gurevich, D. Hanson, R. S. Archer, K. Tawara and G. Asahara, A. Phillips and E. S. Davenport, A. Hayes and co-workers, A. Smits, and M. S. Fischer and J. M. Robertson hold that the graphite or free carbon

is not produced by the dissociation of the carbide *per se*, but rather separates directly from solid soln. R. A. Hadfield, W. H. Hatfield, J. E. Hurst, H. M. Howe, R. S. Archer, P. D. Merica, G. S. Scott, E. Heyn and O. Bauer, and G. P. Royston showed that in the reverse process graphite can redissolve when cast iron is heated, without the intervention of the free carbide stage, to form, presumably, a solid soln. Similarly, also, it is not improbable that the solid soln. can deposit graphite directly. Free ferrite can thus be formed by the reduction in the conc. of the solid soln. as it deposits graphite, and by the resolution of the solid soln. into ferrite and pearlite as it passes through the pearlite transformation.

R. Ruer and R. Klesper showed that δ-iron dissolves about 0·07 per cent. of carbon at the peritectic temp. 1486°. T. D. Yensen observed that iron with 0·003 per cent. of carbon at ordinary temp. contains a trace of cementite. Hence the solubility of carbon in α-iron is very low, but not zero. H. Scott observed that with iron containing less than 0·03 per cent. of carbon no break can be observed corresponding with the A_1-arrest; and F. Yamada showed that no eutectoidal mixture is formed when less than 0·034 per cent. of carbon is present, but appears as an intercrystalline film in slowly-cooled specimens. K. Tamaru, acting on the assumption that the solubility of carbon in α-iron at the A_1-arrest is 0·034 per cent., inferred that since α-iron and δ-iron have a similar space-lattice, the solubility of carbon in δ-iron lies on a continuation of the solubility curve of carbon in α-iron *PMO*, Fig. 95. *MN* denotes the eutectoidal horizontal. Fig. 95 then represents the position of the equilibrium curves at the extreme left of the equilibrium diagram of the iron-carbon alloys.

A. Sauveur and V. N. Krivobok said that the **solubility of carbon** in α-ferrite, slowly cooled, is about 0·06 per cent. of carbon in soln. at ordinary temp.; A. Sauveur, basing his statement on the non-observance of cementite in certain carbon steels, said that ferrite or α-iron can dissolve 0·06 per cent. of carbon; C. Benedicks gave 0·27 per cent.; whilst W. H. Hatfield gave 0·04 to 0·05 per cent. These numbers are doubtless too high for ordinary temp. F. Yamada gave 0·01 per cent.; T. D. Yensen, 0·006 to 0·008 per cent.; H. Scott, <0·03 per cent.; J. H. Whiteley, 0·03 per cent.; N. B. Pilling, 0·015 per cent.; K. Tamaru gave 0·034 per cent.; and A. Bramley and F. W. Haywood, 0·04 per cent. The subject was also discussed by F. Wever, H. A. Dickie, K. Daeves, N. J. Wark, G. Charpy and A. Cornu-Thénard, J. A. Holden, I. Iitaka, and N. Seljakoff and co-workers. According to J. H. Whiteley, carbon is soluble in α-iron at temp. exceeding 630°; and it can be retained ih solid soln. by quenching. On tempering at or below 250° the precipitation of cementite occurs in the ferrite grains, and as the temp. rises the minute particles migrate to the boundaries of the grains. The speed of movement is rapid at 550°. Above 630° the solubility of carbon in ferrite gradually increases with temp., and at 720°, 0·03 per cent. is dissolved. As the purity of the ferrite is diminished, the initial temp. for soln. rises a little, and at the same time the solubility of carbon is, in all probability, correspondingly reduced. Carbon is not insoluble in iron, even at ordinary temp., and T. D. Yensen stated that up to about 0·008 per cent. is retained in soln. O. C. Ralston gave 0·003 per cent. for the solubility of carbon in α-ferrite at ordinary temp., and S. Tamura observed 0·034 per cent. at about 720°; the maximum solubility in δ-iron at about 1482° is 0·07 per cent. W. Köster gave the curves, Fig. 96, for the solubility of carbon in α-iron. R. Ruer and J. Biren observed that the solubility of graphite in molten iron rises linearly with temp. from 1152° to 1700°; it then bends away from the concentration axis, slightly at first, and then more strongly as the temp. rises. The concentration at the graphite eutectic, 1152°, is 4·25 per cent. of carbon, and at the cementite eutectic, 1145°, it is 4·30
Fig. 96.—The Solubility of Carbon in α-Iron.

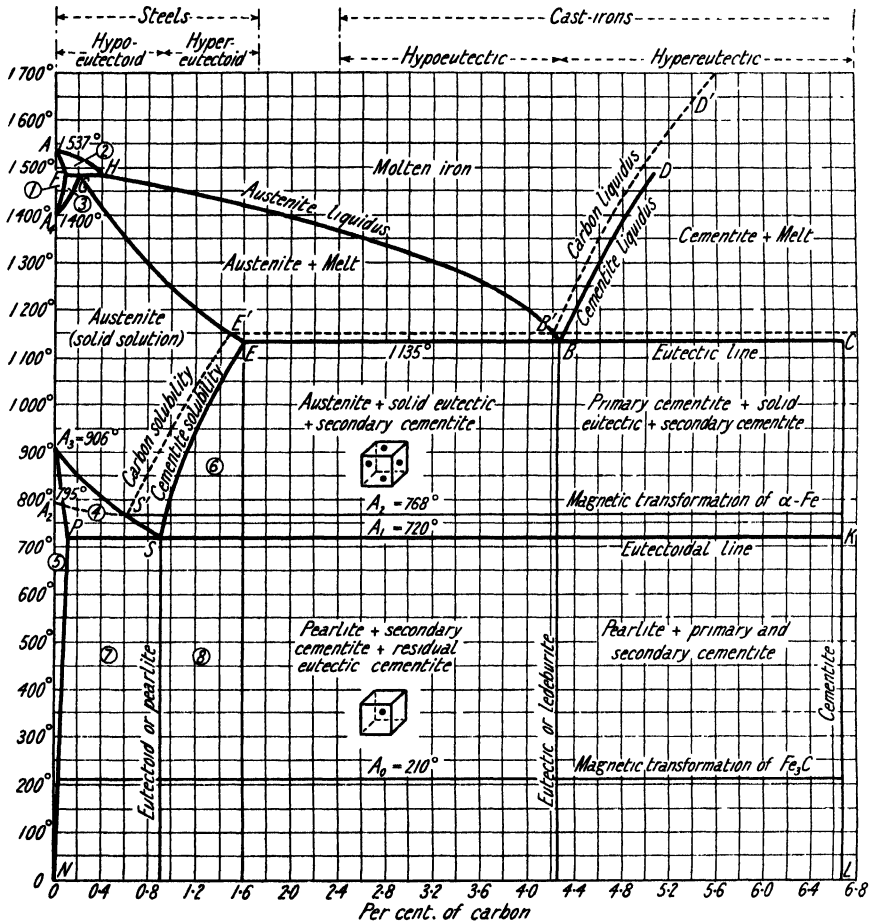
per cent.—*vide* **5.** 39, 20.   K. Schichtel and E. Piwowarsky found that phosphorus, silicon, and nickel lower the solubility of carbon in iron.   With over 2·5 per cent. of phosphorus, 3 per cent. of silicon, and 15 per cent. of nickel, the effect on carbon ceases.   At 1200°, 0·29 part of carbon is thrown out for every one part of phosphorus, 0·28 part of carbon for one part of silicon, and 0·045 part of carbon for one part of nickel ; at 1700° the corresponding parts of carbon separated are 0·42, 0·40, and 0·045 respectively—*vide* the chemical properties of iron, and the alloys of silicon, and nickel.   E. M. Wise, and H. L. Maxwell and A. Hayes discussed the solubility in austenite of carbon from the element, and from carbide ; and


Fig. 97.—Conventional Phase Diagram of the System : Carbon-Iron.

G. Charpy, C. Benedicks, and S. Konobejewsky, the solubility of iron in graphite. G. Sirovich supposed that there are two ferrites, one stable below and the other stable above 370° ; the former dissolves cementite or carbon, and the latter not so.

The rate of diffusion of the dissolved carbon (*vide infra*) is very rapid at the A_1-point.   During slow cooling the dissolved carbide is deposited on the existing crystals, so that slowly cooled ferrite in ordinary steels contains very little, if any, carbon in solid soln.   The presence of dissolved carbon in α-iron increases its Brinell's hardness to a small, but definite, extent.   Thus, untreated steel and steel quenched from 550°, 680°, and 980° had the respective hardnesses, 89, 91, and

105. F. Sauerwald and A. Koreny discussed the rate of dissolution of graphite in molten iron.

Fig. 97 can be taken as the conventional phase equilibrium diagram of the carbon-iron system. The diagram, however, has not yet assumed its final form ; and it must be understood that it leaves for discussion many anomalies whose significance has not yet been interpreted. Results obtained with commercial irons do not always fit the diagram, and this is taken to mean that in many cases equilibrium conditions have not been attained. The steels include the alloys with up to about 1·7 per cent. of carbon, and the cast irons begin with about 2·2 per cent. of carbon. There is a more or less ill-defined border-land in between, and the upper limit for cast irons is more or less indefinite and is probably near that of the composition of cementite, namely 6·67 per cent. of carbon. Area (1) includes δ-ferrite with a maximum carbon solubility of 0·07 per cent.—the point F; area (2) includes δ-ferrite and the molten alloy; area (3), δ-ferrite and austenite; area (4), α-ferrite and austenite; area (5), α-ferrite with a maximum carbon solubility of 0·034 per cent. ; area (6), austenite and proeutectoid cementite ; area (7), proeutectoid α-ferrite and pearlite ; and area (8), proeutectoid cementite and pearlite. The temp. of the magnetic transformation of cementite, A_0, is 210°, and the temp. of magnetic transformation of α-ferrite, A_2, is 795°. The temp. of the A_1-arrest, where the eutectoid of solid austenite splits into α-ferrite and cementite, is 720°. The temp. of the A_4-arrest, where δ-ferrite is transformed into γ-ferrite, is 1400°. The m.p. of iron is taken as 1535°. The point N representing the solubility of carbon, as cementite, at room temp., corresponds with 0·003 per cent. of carbon, and NP represents the solubility curve with a rise of temp. The composition of the α-ferrite crystals which separate from austenite is represented by A_3P ; whilst that of austenite in equilibrium follows along A_3S. The temp. of the peritectic FH is 1486°, and the peritectic G corresponds with 0·18 per cent. of carbon—K. Honda gave 0·38 per cent. The curve A_4E is where δ-ferrite separates from the alloy, and A_4G where austenite solid soln. separate out. The eutectic mixture of cementite and austenite, B, is ledeburite, and the eutectic B' refers to the mixture of graphite and austenite ; SE is the solubility curve of cementite, and $S'E'$ that of carbon in austenite. E. Scheil worked out a tentative equilibrium diagram varying both temp. and press. Observational data, however; are too meagre to make this much more than a speculation.

T. D. Yensen argued that pure iron has never been examined. Electrolytic iron contains 0·005 per cent. of carbon, and up to about 0·4 per cent. of oxygen. Carbon, oxygen, and nitrogen here act as interstitial elements in that they occupy the open spaces between the solvent atoms. The effect of these elements is to favour the change from the body-centred to the face-centred cube. These interstitial elements are more soluble in the γ-iron with its face-centred cube than in α-iron with its body-centred cube. As a result, it is inferred that if all the elements whose atoms enter the lattice of the solvent occupy the open spaces, the iron would not change into the γ-form. The corresponding change necessary in the equilibrium diagram is illustrated by Fig. 98, where the dotted lines indicate the effect of this hypothesis on the conventional equilibrium diagram.

FIG. 98.—Constitutional Diagram of the Iron-Carbon Alloys—Low Carbon.

The critical temperatures of the iron-carbon alloys.—The m.p. of purified iron

is somewhere between 1528° and 1537°. The presence of carbon lowers the m.p. down to the eutectic at about 1135°.

The A_4-point.—According to S. Tamura, the A_4-arrest of iron is raised from 1400° to 1486° by the dissolution of 0·07 per cent. of carbon ; whilst K. Honda said that only the iron-carbon alloys with less than 0·38 per cent. of carbon can exhibit the A_4-arrest. With more carbon δ-iron passes into γ-iron, that is, the solid soln. of carbon in δ-iron passes into a solid soln. of carbon in γ-iron.

The A_3-point.—R. H. Harrington and W. H. Wood said that there is about 6° difference in the A_3-transformation in heating and cooling ; the transformation seems to occur in two stages. H. M. Howe and A. S. Levy discussed the position of the A_3-arrest with carbon steel in a state of equilibrium. He took 917° as the normal value for this arrest, and gave for the temp. T of the A_3-arrest with C per cent. of combined carbon, $T°=917-306C$. The subject was discussed by G. K. Burgess and co-workers, A. Stansfield, K. W. Zimmerschied, H. le Chatelier, A. Sauveur, and P. Bardenheuer. Carbon raises the A_4-arrest, and lowers the temp. of the A_3-arrest of iron from its normal value, 906°. The lowering which the A_3-point undergoes with increasing proportions of carbon is represented by the curve A_3S, where S represents the eutectic between α-iron and cementite. With higher proportions of carbon, the A_3-arrest coincides with the A_1-arrest. Those who regard β-iron as a definite allotrope, regard the A_3-arrest as the temp. or range of temp. within which γ-iron passes into β-iron, and the line where β-ferrite is liberated from the solid soln. of carbon in iron. The separation of β-iron continues down to the A_1-arrest. As the proportion of carbon increases, the A_3- and A_2-arrests merge into the A_1-arrest. The abrupt changes in physical properties which occur when the cooling alloy passes through the A_3-arrest become less marked as the proportion of carbon increases. The solvent power of the alloy for carbon is also reduced on cooling through this range of temp.

The A_2-point.—On passing the A_2-arrest, iron or steel with less than 0·35 per cent. of carbon suffers a transformation of α- to β-iron at about 768°. F. Osmond thought that α- and β-iron are isomorphous ; this is true if they are two distinct chemical individuals. In spite of the changes which occur in the physical properties as it passes through the A_2-arrest, it is generally held that no new allotrope is formed. The crystalline structure of the β-form is the same as that of the α-form. In any case, the A_2-arrest represents the temp. of magnetic transformation where ferromagnetic α-iron changes into paramagnetic α-iron on the heating curve, or conversely, on the cooling curve. The term paramagnetic α-iron is here used in place of β-iron— *vide supra*. The solvent power of iron for carbon is also reduced on passing through this range of temp.

The $A_{3,2}$-arrest.—The Ar_3-arrest merges into the Ar_2-arrest with steels containing between 0·35 and 0·85 per cent. of carbon. R. H. Harrington and W. H. Wood found that the merging of the A_3- and A_2-arrests occurs at 744° when the steel has 0·60 per cent. of carbon. The $A_{3,2}$-arrest marks the beginning of the liberation of iron which continues between the $Ar_{3,2}$- and the Ar_1-arrest, and it also marks the passage of iron from the β- to the alleged α-state, or directly from the γ- to the α-state. The changes as the alloy cools past the $A_{3,2}$-arrest are similar to those taking place with lower carbon steel at A_3- and the A_2-arrests, namely, liberation of α-ferrite, a change in the thermal expansion, in the tensile strength, sp. ht., electrical resistance, and magnetic susceptibility. There is also a loss in the solvent power for carbon.

The A_1-point.—H. M .Howe discussed the position of the A_1-arrest with carbon steel in a state of equilibrium. The recorded data vary from 700° to 731°, and he considered that the most reliable results fall between 715° and 723°. He gave 723° for the best representative value. S. W. J. Smith and J. Guild gave 735° for the Ac_1-arrest, and added that the value is the same for all steels. A. Hultgren said that the transformation which occurs in the Ac_1-range is influenced by (i) the presence of alloy elements ; (ii) the heterogeneity which occurs on solidification ;

and (iii) the slow rate of diffusion of carbon, and possibly other elements, present in the austenite. The arrest at about 723° occurs with hypoeutectoidal steels, or the $A_{3,2,1}$-point of hypereutectoidal and eutectoidal steels corresponds with the fairly sudden and spontaneous transformation of the residual solid soln. of austenite of eutectoidal composition into pearlite. The A_1-arrest is not generally associated with critical variations of the electrical, magnetic, and other properties of the alloy.   On passing the $A_{3,2,1}$-arrest there is a marked thermal expansion which is a maximum with eutectoidal steel, a sudden decrease in electrical resistance, a sudden gain of magnetization, a loss in solvent power for carbon, and a temporary gain in malleability. The Ar_{cm}-arrest with hypereutectoidal steels indicates the beginning of the separation of cementite along the ES-line of the equilibrium diagram ; and the Ar_G-arrest, the beginning of the separation of graphite along the $E'S'$-line.   The PK-line in the equilibrium diagram is horizontal, but observations generally show an upward slope corresponding with a rise of 20°. This is thought to be an effect of silicon, which is usually present as an impurity and which is known to raise this point—whilst it is lowered by manganese. K. Tamaru showed that at this temp. α-iron has its greatest solvent power for carbon, for it dissolves 0·034 per cent. At this temp. γ-iron can dissolve 0·9 per cent. of carbon. K. Honda observed that with the rapid cooling of high-carbon steels through the A_1-arrest, the transformation occurs in two stages : (i) the conversion of γ- to α-iron ; and (ii) the separation of carbon from a supersaturated soln. in α-iron. The latter stage can be suppressed by sufficiently rapid cooling—*vide infra*. S. Konno, A. Hayes and W. J. Diederichs, J. A. Jones, and T. Murakami studied the effect of the rate of cooling, etc., on the A_1-arrest. B. Kjerrman found that in the absence of manganese, or other alloying element, the Ac_1-arrest occurred at a definite temp. or over a very small range. Anomalies were attributed to the presence of non-metallic inclusions—thus, manganese depressed the beginning of the pearlite interval, and widened the range ; silicon raised the interval and extended it. In a silicon manganese steel the interval was doubled. Heat treatment tending towards homogeneity of structure reduced the range caused by manganese, but did not affect the range caused by silicon. The effect of these two elements is explained on the assumption that at the same temp. manganese is more and silicon is less soluble in austenite than in ferrite. Phosphorus behaves like silicon.

The A_0-point.—This arrest does not occur with iron alone ; but it resembles in many respects the A_2-transformation with iron alone. It begins at 215° to 200° on the cooling curve and extends 50° to 60° downwards. It ends at 215° on the heating curve. Heat is evolved on cooling and absorbed on heating through this point. Above 205° cementite is paramagnetic. The A_0-arrest represents the beginning of the transformation of cementite from a paramagnetic to a ferromagnetic state, or conversely, S. Curie showed that this reversible transformation occurs at about 200° in iron-carbon alloys. No change was observed by F. Wever in the space-lattice of the crystals as the alloy passes through this critical temp. This A_0-arrest was observed by S. Wologdine, and studied by P. Dejean, S. W. J. Smith and J. Guild, P. Chevenard, and K. Honda and H. Takagi, who placed it at 210°, while T. Ishiwara, and I. Iitaka placed it at 215°. M. G. Morris and H. Scott found changes occurring in the sp. ht. in pearlitic and in high-carbon steels at this temp. The actual point depended on the rate of heating and the carbon content, both of which raised the thermal point; the Ac_2-arrest occurred at 191° to 207°, and the Ar_0-arrest, at 199° to 205°. I. Iitaka observed that with the electrical resistance, singularities occurred corresponding with the Ac_0-arrest at 195° to 212°, and the Ar_0-arrest at 192° to 200°. G. Tammann and K. Ewig found that the A_0-arrest occurs at room temp. when 0·5 per cent. of boron or 10 per cent. of manganese is present. Both these substances dissolve in the carbide, whereas substances like gold which dissolve in iron alone, but not in the carbide, do not affect the A_0-arrest of steels—*vide infra*, cementite. K. Tamaru

found that the magnitude of the A_2-transformation, when observed magnetically, depends on the form of the cementite.

Other critical temperatures.—Quite a number of observers have reported critical changes in different physical properties of iron at temp. below 400°. For example, G. Borelius and F. Gunneson,[2] and G. Belloc observed critical temp. in the rate of removal of occluded hydrogen and nitrogen ; and W. C. Roberts-Austen noted an anomaly due to the presence of hydrogen ; J. H. Andrew and co-workers observed thermal changes at 60° to 150° ; and H. C. H. Carpenter and B. F. E. Keeling, an anomaly at 616°. G. Sirovich showed that at about 370° the A_0-arrest corresponds with a polymorphic transformation of a_1-iron ; a_1-Fe $\rightleftharpoons a_2$-Fe. Both forms of a-iron have a characteristic coefficient of expansion. The Bureau of Standards could not verify G. Sirovich's deductions other than to show that the X-radiograms indicated that near 370° there is a recrystallization of some amorphous metal ; and H. S. Rawdon and co-workers attributed the effect to the reducing action of hydrogen on the contained iron oxide, and the recrystallization of the fine-grained iron so obtained. As indicated below, there is a minimum in the torsional elastic limit at about 370°, and a peak in the electrical conductivity curves at about 350°. B. D. Enlund, G. E. Svedelius, P. Chévenard, T. Matsushita and K. Nagasawa, G. Charpy and L. Grenet, C. Grard, K. Honda, and K. Tamaru observed changes in the sp. vol. or sp. gr. at about 130° and about 280° ; J. H. Andrew and co-workers observed an expansion at 60° to 150°. F. Robin reported singular points in the hardness at 100° and 250° ; F. Fettweiss, and K. Tamaru, at about 600°. E. G. Herbert, D. Smith, and I. Hey, and S. S. Vanick and T. H. Wickenden observed critical points in the work-hardening of iron at different temp., and in the annealing temp. and hardness curves. M. Ishimoto measured the viscosity or internal friction of iron from the damping ·of vibrations at different temp., and found a minimum in the curve at 65°, a maximum at 170° to 183°, and a break at 260°. The hardness curves were found to be parallel with those of the internal fraction. C. E. Guye and S. Mintz found singularities in the viscosity of wires at 180° and 240° ; G. Wertheim, in the velocity of sound in wires at 100° ; and G. Chrystal, and F. Robin, in the acoustic properties at 120° and 250°. F. Robin suggested that the singularity in the acoustic tests of iron between 100° and 250° shows that a-iron really exists in two forms, a_1-iron and a_2-iron. As indicated above, the A_2-arrest sometimes shows a double peak on the curve. The cause is not clear. It is not to be confused with the splitting of the A_1-arrest discussed later. M. le Blant observed discontinuities in the tensile elastic limit at 100°, and between 250° and 300°—though F. Robin does not think this test of much importance, but he concluded that, in general, static stresses indicate a point of transformation between 100° and 250°, and dynamic stresses, between 300° and 450° ; F. C. Lea and O. H. Crowther, in the maximum tensile strength and yield point at 300° ; F. C. Lea, in the tensile strength of armco iron since there is a maximum at 230°, and in the elongation there is a maximum at 350° and a minimum in the tensile elastic limit at 230° ; and in mild steel, in the torsional rigidity modulus at 120° and 230°. O. Reinhold, H. J. French, Z. Jeffries, K. Honda, and T. Inokuty also observed a maximum between 200° and 300°. A. Goffey and F. C. Thompson found critical points in the torsional elastic limit at 70°, 120°, 170°, 230°, 290°, and 310° and 350°. E. L. Dupuy found that a maximum in the tensile strength occurs at 250° and a minimum in the reduction of area at 250° with 0·15 per cent. carbon steels, but this rises to 330° with 0·91 and 1·25 per cent. carbon—but in these two high-carbon steels no minimum was observed in the reduction of area ; G. Charpy, R. H. Greaves and J. A. Jones, and L. Guillet and L. P. M. Revillon noted one in the notched-bar brittleness at 100° to 150°.

K. Honda, and K. Honda and H. Takagi observed a thermal change between 130° and 215°, and between 220° and 280° ; K. Gebhard and co-workers, a break at 860° ; A. Perrier and F. Wolfers observed a break in the heating curve at 113° ;

and H. G. Movius and H. Scott, at 120°, 140°, 160°, and 200°; C. Benedicks observed a break in the thermal expansion curve at 830°; and he thought that this supported the singularity observed by P. Weiss and G. Foëx in the magnetic curves (q.v.). F. C. Thompson, J. H. Andrews and co-workers observed an expansion between 60° and 150°; and R. Ariano, A. Nouel, F. Robin, G. Sirovich, and J. Driesen also observed breaks in the expansion curve. The results were criticized by F. Rapatz, and H. S. Rawdon and co-workers. A. Perrier and F. Wolfers, and J. Maydel found many irregularities in the heat capacity curves —e.g. one at 800° and one at 1100°; J. A. Harker, and J. Pionchon, in the sp. ht. at 320°; P. Oberhoffer, at 320°; W. H. Dearden, at 115°; N. Stücker, at 200°, 250°, and 300°; and E. H. and E. Griffiths, at 66°.

P. Saldau observed breaks in the electrical resistance curves. W. Broniewsky found a slight bend in the electrical resistance curve at 850°, as well as at 750° and at 950°. B. D. Enlund, in the electrical resistance at about 100° and 250°; K. Honda, at about 130° and 280°; and J. H. Andrew and co-workers, between 60° and 150°; F. C. Thompson and E. Whitehead, in the electrical resistance and thermoelectric force against platinum at 55°, 100°, 120°, 140°, 220°, 245°, etc.; A. Goffey and F. C. Thompson, in the electrical resistance at 70°, 120°, 170°, 230°, 290°, 310°, and 350°; G. Borelius and F. Gunneson, G. Borelius, G. Belloc, and W. Heræus, in the thermoelectric force (q.v.); D. K. Morris, in the magnetic properties at 150°; K. Honda, at about 130° and 280°; W. H. Dearden and C. Benedicks, at 120°; J. H. Andrew and co-workers, between 50° and 150°; C. Maurain, at 180° and 300°; and S. R. Roget, at 135°; F. C. Thompson, at 830°; and S. W. J. Smith, and K. Honda and H. Takagi, in the magnetic permeability of white and grey cast iron and high-carbon steel—a change commenced at about 160° and was completed at 215° on heating, and on cooling it started at 215° and finished at 160°; the magnitude of the change was roughly proportional to the percentage of free cementite; the temp. of 160° varied with the strength of the magnetizing field. R. Forrer and J. Schneider observed that the forms of iron produced by annealing the quenched metal at 200° to 400°, and at 450° to 900°, have different magnetic properties, and he accordingly supposed that iron exists in two forms, both stable at ordinary temp.

The cause of these low temp. changes is unknown; C. Benedicks, and Z. Jeffries suggested that they are due to allotropic transformations, although C. Benedicks showed that a definite temp. may not be necessary for one element to change into another, and he assumed that an allotropic change begins at about 100° and extends up to about 400°. It is, however, not clear whether a number of distinct changes occur, or whether the phenomena are the result of one long continuous process. Changes at 160° and 200° are due to the carbide or cementite, because they are not present when carbide is absent—vide supra. The magnetic transformations are discussed in connection with magnetism—vide infra. K. Honda attributed the change at about 130° to the decomposition of martensite whereby cementite is precipitated, but later showed that it is more probably due to the change of α- into β-martensite; the precipitation of cementite from martensite occurs between 220° and 280°. A satisfactory explanation for the other singular points on the curves is not known; some of the singularities are due to secondary actions—vide supra for effects due to occluded gases.

G. Borelius and F. Gunneson obtained such a number of singular points that they arranged them in groups about a central one—e.g. the Z-changes included the singularities Z_3, Z_4, Z_5, . . . They considered that there is a periodicity about these points, and they give an expression connecting the temp., T, with the numerical suffix, n, of the point; thus, for iron, $T_n=97_n$, where n ranges from 3 to 12. It is assumed that the Z-changes occur when the number of atoms, r^{-1}, bearing a number of energy quanta equal to or greater than the numerical suffix of the change, n, is one-fourth of the total. When one-fourth the atoms have their respective number of quanta increased by one, a Z-change occurs. The hypothesis

is arbitrary, and is not based on known facts. G. Auchy attempted to explain the different properties of the iron-carbon alloys on the assumption that different ferrated carbides are involved in the various states.

A. Goffey and F. C. Thompson consider that the changes are intra- not inter-atomic or inter-molecular; and that they are produced by alterations in the arrangements or movement of the electrons about the positive nucleus of the atom, and are closely connected with the characteristic vibration frequency of the atom. Indeed, it can be shown that a decrease in the frequency of vibration of the iron atom in the neighbourhood of 300° can bring about (i) an abrupt rise in the electrical resistance, (ii) a fall in the bulk and rigidity modulus, and (iii) an abrupt rise in the sp. ht. at constant vol. If the effects are due to changes in the structure of the iron atom, it follows that the iron atom must be in a very unstable state. The magnetic property of iron may be due to a peculiar electronic arrangement which is very unstable with respect to changes of temp.

§ 15. The Constituents of the Iron-Carbon Alloys

It was once postulated by chemists as axiomatic that " the particles of a solid are incapable of fundamental readjustment; they are too rigidly braced together. Their mutual bonds are too close to permit the necessary shiftings." The converse proposition describes exactly an extraordinary variety of changes, dependent on atomic movements and rearrangements, which take place in the iron-carbon alloys while they are in the solid state. There are various forms of the solid soln. of carbide or cementite in iron, which can be more or less fixed at ordinary temp. by the abrupt chilling or quenching of the alloy from particular temp. J. M. Robertson [1] discussed the effect of variations in the rate of cooling on the structure of steel; and general observations on the microstructure were made by J. E. Howard, A. Sauveur and H. C. Boynton, J. J. Kessler, R. Adam, A. Bencke, G. Delbart, H. M. Boylston, E. A. Schott, J. Boiteux, J. Mitchell, and numerous others indicated below. Collections of photomicrographs were made by E. L. Reed, and H. Hanemann and A. Schrader.

As indicated above, a solid soln. of iron tritacarbide or cementite in γ-iron was called by F. Osmond **austenite**—after W. C. Roberts-Austen. C. Benedicks regarded austenite as a supercooled solid soln.; and the subject was discussed by O. E. Harder and R. L. Dowdell, and J. H. Whiteley. There are two opposing hypotheses as to the state of the carbon in solid soln. in austenite; in one—Z. Jeffries and R. S. Archer—the solute is supposed to be carbon interstatically located in the face-centred lattice of γ-iron; and in the other—A. Sauveur—a solid soln. of cementite, Fe_3C, in γ-iron. This agrees with C. P. Yap's thermodynamical study of the system, but an *experimentum crucis* has not been devised. The fact that cementite crystallizes directly from the austenite solid soln. when it is chilled does not prove that cementite existed previously, to any great extent, in the solid soln. J. M. Robertson, and Z. Jeffries and R. S. Archer hold that in austenite, cementite is not in soln. as such, and the evidence is based on the relation between the size of the cementite molecule and of the iron atom. It is known that carbon diffuses in austenite at an appreciable rate, and one school believes that it is not likely that with the relatively large molecules of cementite, where each atom of carbon is loaded with three atoms of iron, the carbon can diffuse easily through the lattice of γ-iron, whereas it is thought that the relatively small carbon atoms should be able to do it easily. Carbon diffusion, however, may be due to a small percentage dissociation of cementite when cementite carries the major portion of the carbon in austenite. Consequently, the general opinion based on the X-ray analysis, etc., by J. H. Andrew, A. Westgren, A. Westgren and G. Phragmen, Z. Jeffries and R. S. Archer, F. H. Jeffery, and E. C. Bain is that austenite is a solid soln. of carbon in γ-iron. On the other hand, H. A. Schwartz added that in view of G. Cesaro's statement that molten iron is a soln. of the tritacarbide in iron, and that cementite separates from the frozen soln. on further cooling, it is doubtful if austenite can be a soln. of free carbon as such. The X-radiograms of S. Shimura led him to conclude that the carbon is present in austenite in the form of neutral atoms—*vide infra*; and S. Sato concluded that the space-lattices of quenched steel and of carbon in soln. as carbon or as cementite are all the same. When a quenched steel is tempered at 300°, cementite is liberated and decomposed into iron and carbon. In hypereutectoid steels a similar decomposition of the carbide occurs above the Ac_1-arrest.

The equilibrium diagrams show that austenite may contain any proportion of carbon from a trace up to 1·7 or maybe 2·0 per cent. Austenite with the higher proportion is said to be saturated with carbon. Steels usually contain less than 1·7 per cent. of carbon, so that the austenite in such steels is unsaturated, but cast iron has generally more than 1·7 per cent. of carbon, and in such cases the austenite is always saturated. H. M. Howe called a soln. of γ-iron with 1·7 per cent. of carbon *austenoid*. Austenite is stable within the region bounded by the lines GA_4A_3SE in the equilibrium diagram of the iron-carbon alloys, Fig. 97. As the alloy passes from the γ- to the α-state it deposits cementite, for the resulting α-iron dissolves only about 0·05 per cent. In consequence, as iron changes from γ-state to the β-α-state, the progressive lowering of the temp. of the transformation is represented by the line A_3S' as the proportion of carbon increases from a trace to 0·85 or 0·9 per cent., and with 0·85 to 1·70 per cent. carbon the temp. of the allotropic change is constant, and is represented by the line SK. In no case is the austenite stable below the temp. represented by SK, and it is therefore not stable at atm. temp., although it is possible to prevent almost the whole of the austenite from being transformed by a very rapid quenching of a high-carbon steel.

The austenite obtained by quenching iron-carbon steel is always accompanied by some martensite—*vide infra*. Thus, J. A. Mathews found that some austenite always escapes conversion to martensite in the hardening of medium or high-carbon steels ; and in the case of alloy steels, more escapes conversion after oil-quenching than after the water-quenching. H. Scott, A. Baykoff, L. Guillet, M. A. Grossmann, W. J. Kurbatoff, and K. Heindlhofer and F. L. Wright also observed that austenite persists in high-carbon steels, and B. D. Enlund, in low-carbon steels. The austenite that escapes conversion is called *retained austenite*. J. A. Mathews showed that the retained austenite is a contributing cause to the increased permanence of retentivity of permanent magnetic steels, and in many alloy steels not used for permanent magnets. When some metals are alloyed with the iron—say 14 per cent. of manganese or 25 per cent. of nickel—the transformation temp. of γ-iron is lowered to atm. temp. or less. Hence, austenite alone can be obtained under these conditions. As just indicated, austenite alone cannot be produced in carbon steels by quenching, but this structure can be obtained in the presence of a certain proportion of manganese. K. Tamaru gave Fig. 99 to show the relative proportions of carbon and manganese required to obtain the austenitic structure by quenching steel in water. When only a trace of carbon is present, over 16 per cent. of manganese is required, whereas with 2 per cent. of carbon, 5 per cent. of manganese suffices. Since austenite is paramagnetic and the other structures are ferromagnetic, the purity of austenite can be detected by a magnetometer. For the transformation of austenite to martensite, troostite, and pearlite—*vide infra*.

FIG. 99.—The Proportions of Manganese and Carbon required to produce Austenite by Water-quenching.

Under the microscope austenite appears as a mass of white, polyhedral grains. Fig. 100, by F. T. Sisco, represents a photograph of austenite. The carbon of austenite makes no lines in the X-radiogram, and this means that the carbon is present either in random positions scattered through the lattice, or else it displaces random iron atoms in the lattice. A. Westgren and co-workers observed that the X-radiogram of austenite, like that of γ-iron, corresponds with a face-centred cubic lattice : whilst the side of the cubic lattice of γ-iron is $a=3·60$ A. at 1100°, and 3·68 A. at 1425° ; the value of a for austenitic steel with 0·24 per cent. of carbon, quenched from 1000° in water, is 3·56 A., and with 1·18 per cent. carbon steel, 3·64 A. Consequently, unlike ferrite, the meshes of the γ-iron lattice of austenite are widened by the dissolved carbon. K. Honda and S. Sekito found the lattice constant $a=3·596$ A. for steel with 0·202 per cent. carbon ; 3·604 A. for 0·508 per

cent. carbon ; and 3·607 A. for 1·075 per cent. carbon. It is inferred that the solid soln. is not formed by the simple substitution of the metal atoms in the lattice by carbon atoms, but that the carbon atoms are distributed according to the laws of probability within the lattice in the interstices between the metal atoms which occupy all the points of the face-centred lattice. This also agrees with F. Wever and P. Rüttens' studies on manganese steels, etc. O. E. Harder and R. L. Dowdell made observations on the X-radiograms of austenite.

N. Seljakoff and co-workers found the sp. vol. of austenite increased with increasing proportions of carbon ; and F. Wever made observations on this subject with manganese steels. K. Honda and S. Sekito represented the sp. vol. of austenite by $v=0·1257+0·0003C$, where C denotes the percentage amount of carbon. They observed for the sp. vol. :

Carbon .	0·202	0·396	0·508	0·602	0·73	0·895	1·04	1·075 per cent.
Sp. vol..	0·1257	0·1260	0·1259	0·1259	0·1259	0·1259	0·1260	0·1259

Austenite is comparatively soft, being but slightly harder than ferrite. According to H. C. Boynton, the hardness of austenite is 1·06 when that of ferrite
FIGS. 100 and 101.—Austenite Grains in Steel (× 500)—after F. T. Sisco ; and in Manganese Steel (× 50)—after A. Sauveur.

is unity—*vide infra*, hardness. K. Tamaru gave 155 for Brinell's hardness. Austenite is non-magnetic. H. Hanemann said that the austenite in steel is isotropic.

It has been shown—**1.** 11, 4—that as the molten metal solidifies, it first assumes a cellular structure. *La théorie cellulaire de l'acier* was discussed by F. Osmond and J. Werth. Crystallization starts about numerous nuclei, and the crystals grow in three dimensions until arrested by neighbouring growths. The growing crystals are so crowded that there is not sufficient space for them to develop their regular crystal form ; in consequence, a compact mass of irregularly shaped crystals is formed. The polyhedral crystalline grains, or simple grains, make the metal appear as if it had been built up in the form of a mosaic with irregularly shaped stones. No subsequent treatment is able to destroy this completely, because the impurities, which accumulated at the surfaces separating the grains as they are formed, always remain *in situ*. As indicated below, if the steel is held for a long period at a temp. above the critical range, the austenite grains grow in size. If two adjacent grains have the same orientation, the boundary may disappear, and the two grains may merge into one. W. J. Brooke and F. F. Hunting found that armco iron (99·84 per cent. Fe) or Swedish iron (0·04 per cent. C) on cooling passes through a brittle range between 900° and 800°, but not during

heating. A eutectic or eutectoid structure appears in the metal quenched from between these temp., but is absent from metal quenched from above or below the brittle range. This constituent resembles pearlite in structure, but is not related to the carbon content, and is independent of the proportion of oxide in the iron.

J. O. Arnold criticized the existence of an austenite as defined above; and W. H. Hatfield proposed that the term austenite be employed for the saturated matrix on passing the Ac_1-arrest when a further absorption of the carbide of super-saturation has begun. The theory of labile and metastable soln.—1. 9, 6—was applied to the primary crystallization of austenite by A. F. Hallimond.

Austenite occurs in supersaturated iron-carbon alloys at high temp. in the constituent hardenite, sometimes named martensite, when it has, at high temp., increased its carbon percentage by its solvent action on the neighbouring carbide. It denominates that portion of a heat-treated mass which changes in composition with each variation in temp. above the point of diffusion of carbide in hardenite.

As previously indicated, H. A. Schwartz applied the term *boydenite* to stable solid soln. of carbon and iron in contradistinction to the term *austenite* for the metastable solid soln. of cementite or carbon in austenite, or the term may be used without implication as to the nature of the solute. In boydenite, the carbon atom is supposed to replace one of the iron atoms in the face-centred lattice, whereas in austenite the carbon atoms are supposed to be scattered in the interstices of the lattice. The evidence for the metallographic individuality of boydenite is not conclusive. H. A. Schwartz holds that the stable and metastable systems of boydenite and austenite differ in the maximum carbon concentration at a given temp., and also for a given conc. of carbon in their electrical resistance, and in the location of the A_1- and A_2-arrests. In view of A. Westgren and G. Phragmen's, and F. Wever's demonstrations (*vide infra*) that in austenite the carbon atom is located within the crystal cell or space-lattice and does not occupy any position normally belonging to the iron-atoms, H. A. Schwartz examined the hypothesis that in the solid soln. of carbon in iron known as austenite, the carbon is additive in the space-lattice, and substitutional in boydenite. With an altered lattice parameter, in the former case, the density of the austenitic solid soln. will increase, because the carbon atom will add to the mass of the soln. but not to the vol., whereas with the boydenite solid soln. the density will decrease with increasing carbon content, because the carbon atom is higher than the iron atom whose place it occupies. H. A. Schwartz made estimates from known data and calculated 7·535 for the sp. gr. of austenite, and 7·393 for that of boydenite at 900°.

The further discussion of austenite is associated with that of **martensite,** so named after A. Martens by F. Osmond. According to F. Osmond, martensite is best formed when a steel containing 0·2 to 0·8 per cent. of carbon is cooled from above the temp. of the A_3-arrest slowly to the A_2-arrest and then suddenly quenched in a freezing mixture at —20°, so as to prevent the splitting up of the austenite into pearlite, but not rapidly enough to preserve the austenite in its unchanged state. According to F. Osmond, and H. Hanemann, martensite can also be produced by immersing austenitic steel in liquid air. As indicated above, some austenite escapes conversion during quenching; thus K. Tamaru found that steel with 0·71 per cent. of carbon, quenched from 802°, retains 10 per cent. of austenite; steel with 1·19 per cent. of carbon, quenched from 855°, retains 15 per cent.; and steel with 1·48 per cent. of carbon, quenched from 980°, retains 20 per cent. of austenite. The subject was discussed by J. M. Robertson, and by O. E. Harder and R. L. Dowdell in their memoir: *The Decomposition of the Austenitic Structure in Steels* (Minneapolis, 1927).

The decomposition of austenite on quenching.—O. E. Harder and R. L. Dowdell found that in order to preserve a large proportion of austenite at room temp. a high-carbon steel, and preferably an alloy steel, should be used; an oil-quench from a high initial temp. will produce more austenite than a more drastic water-quench at the

same temp. E. Scheil, for instance, obtained the results indicated in Fig. 102 with steels containing 0·93 and 1·05 per cent. of carbon respectively—*vide infra*, pearlite. The slower the cooling, the greater the proportion of retained austenite. This has also been established by the work of J. A. Mathews, W. J. Crook and H. S. Taylor, W. Ischewsky, D. J. McAdam, E. Hess, R. Ruer, A. Hayes and co-workers, O. E. Harder and R. L. Dowdell, E. C. Bain and W. N. S. Waring, J. M. Robertson, E. Scheil, K. Tamaru and S. Sekito, and K. Honda and A. Osawa. If large or small sections are quenched from a high temp., they will contain more austenite than if quenched from a lower temp. At high temp. larger austenite grains are produced. The larger austenite grains have a greater stability than the smaller ones, and it has been observed that the slip-lines or needles produced in a coarse-grained structure are longer and wider, which results in a coarser martensitic structure and gives the appearance of a smaller amount of martensite. The stability of the large grains produced at high temp. is further increased in steels containing an excess of carbides by the larger amount of carbon taken into soln. in the austenite. While the maximum temp. difference between the outside and the inside must be greater in quenching from the higher temp., and the resulting stress greater, the greater the stability of the more concentrated austenite and the larger grain-size. Also, a given amount of stress

Fig. 102.—The Effect of the Quenching Temperature on the Proportion of Retained Austenite.

may be expected to produce fewer slip-lines in a coarse structure than in a fine-grained structure. E. Maurer observed that on cooling, austenite passes into martensite which is different from the martensite produced by tempering. H. Hanemann found that when a portion of a quenched 1·79 per cent. carbon steel with 0·6 per cent. manganese was immersed in liquid air and etched, some needles appeared darker and some lighter than the ground-mass of austenite, while the portion not submerged showed only dark needles. The dark needles were in a tempered condition, and they etched below the surface of the austenite, whilst the whitish, light blue needles were in relief in the light yellow ground-mass of austenite. The light-coloured needles of martensite formed by immersing austenite in liquid air are similar to those formed by ordinary quenching, because the martensite separates out in the Widmanstätten pattern along the octahedral slip planes of the austenite. There is a decrease of approximately 0·1 in the sp. gr. after various specimens had been immersed in liquid oxygen; and the decrease in sp. gr. was attributed to the formation of martensite. When the martensite needles produced in liquid air are tempered, their carbon content is less than that of the mother austenite. When a steel with 1·5 per cent. of carbon and 0·3 per cent. of manganese is quenched from 1050° to 1200°, the martensite predominates near the edges. K. Honda and A. Osawa found that the proportion of austenite retained in the outer layers of a specimen is greater than in the inner part by an amount which increases with rise of quenching temp. and with the proportion of carbon.

According to K. Schröter, a steel containing 1·89 per cent. of carbon and 2·22 per cent. of manganese on immersion in liquid air together with a small magnet is seized by the magnet shortly after immersion. Measurements of the magnetic saturation gave: 1070 gauss for a water-quenched specimen before immersion in liquid air, and 11,380 gauss after immersion; while an oil-quenched specimen gave the respective values 2410 and 14,670 gauss. Similar results were obtained with a 25 per cent. nickel steel. G. Tammann and E. Scheil observed that in cooling hardened steel from 20° to −150° the austenite begins to change into martensite at about −20°, and the conversion continues down to −150°. The change is greater near the surface than within the mass, probably because high internal stresses exert a retarding influence.
D. Lewis observed that if a 0·8 per cent. carbon steel be quenched in a molten salt bath at 232°, austenite is produced, which is comparatively stable for, say, 5 mins., and which will convert to martensite on cooling. The cooling may be slow or rapid without affecting the final hardness—650 on Brinell's scale. When the austenite in a 0·8 per cent. carbon steel decomposes below 232°, the reaction is rapid, and the product is hard martensite; above this temp., up to, say, 316°, the decomposition is comparatively slow and it is not completed in 5 mins. The product has the appearance of martensite, and its hardness is low. It is thought that below 232° crystallization takes place from a labile state, and above that temp. from a metastable state— vide 1. 9, 6. E. S. Davenport and E. C. Bain found that the transformation of austenite in carbon steels is most rapid at about 540°; below this temp. the time required for the transformation increases rapidly. In the range from Ac_1 to 500° the time of transformation decreases with increasing or decreasing proportions of carbon, as the steel departs from the eutectoidal composition. The presence of manganese retards the transformation; and likewise also a small proportion of chromium. As a rule, the lower the temp. of transformation the greater the hardness. According to S. Shimura, the carbon in austenite is present as neutral atoms, but takes on the configuration of cementite with neighbouring ferrite atoms as the austenite changes to martensite, and segregates out as cementite at the A_1-transformation point. The metastable carbon in α-iron—with less than 0·03 per cent. carbon—also takes on the cementite arrangement.

K. Honda and S. Idei, C. Benedicks, and E. C. Bain reported the spontaneous formation of martensite from austenite at room temp.; and H. Hanemann and A. Schrader observed that after a rapidly quenched and polished steel with 1·52 per cent. carbon has stood at room temp. for a short time, martensite appeared here and there in relief on the specimen. C. F. Brush and co-workers observed that in the ageing of martensitic steels at room temp. there is a contraction of about 0·0848 per cent. by vol., and an evolution of heat which reaches a maximum in about 9 or 10 days after the water-quenching at the higher critical temp. A carbon steel quenched from the upper critical temp. gave off 404 cals. per gram during ageing at room temp.—vide infra. A. Meuthen found that the heat of the A_3-transformation is 5·6 cals. per gram, and N. Yamada, that for a eutectoidal steel the heat of the transformation from austenite to martensite is 5·7 cals. per gram. The heat of allotropic transformation of austenite to pearlite obtained by A. Meuthen, and the heat of transformation of austenite to martensite, and of martensite to pearlite obtained by N. Yamada, are as follow :

Carbon	0·38	0·52	0·65	0·70	1·30	1·74 per cent.
Aust. to pearlite	6·8	9·2	11·5	12·4	14·8	13·6 cals.
Aust. to martensite	2·4	3·3	4·1	4·4	5·3	4·8 cals.
Mart. to pearlite	4·4	5·9	7·4	8·0	9·5	8·8 cals.

The results show that the heats of the allotropic transformations increase linearly with the proportion of carbon—vide infra, the thermal properties of iron. K. Honda stated that the first change of the A_1-transformation is really the A_3-transformation, and hence the heat of the transformation of austenite to martensite must be equal to that of the A_3-transformation with pure iron, with a small allowance for the dissolved carbon atoms. A. Schneider, however, found that the heat change during the formation of martensite by quenching is less than that which occurs at the $Ar_{1,2,3}$-arrest. This is due to the fact that a residuum of austenite escapes conversion during quenching, and none of the exothermal reactions, at the $Ar_{1,2,3}$-transition temp., is completed. H. S. Rawdon and S. Epstein stated that the grain-size of martensite is almost entirely determined by the quenching temp.; and J. H. Whiteley added that the size of the martensite crystallites increases with the size of the grains from which they are formed.

P. Dejean, and P. Chévenard observed that the Ar_1-arrest is lowered to 300° or less when a high-carbon steel is rapidly quenched—vide infra. A. M. Portevin

and M. Garvin called this the Ar″-arrest, and supposed that it represents the transformation of austenite to martensite, a change which is accompanied by an evolution of heat and an increase in vol. In the quenching of eutectoidal steels the rate of cooling required to retain the martensite is less drastic than is the case for hypo- or hypereutectoidal steels. The critical rate for a steel with 1·07 per cent. of carbon and 0·08 per cent. of manganese was found to be 6·9 seconds for cooling from 700° to 200° ; with a slower rate of cooling a critical point, the Ar′-arrest, occurred at about 650°, and the core of specimens over 14 mm. diameter contained troostite ; while with a faster rate of cooling the Ar″-arrest, smaller in magnitude than the Ar′-arrest, occurred at 300°, and the alloy contained coarse white needles of martensite in a matrix of austenite. J. A. Mathews observed that with a series of alloy steels the magnetic hardness or coercive force is greater after oil-quenching than after water-quenching, and conversely with the scleroscopic hardness. This indicates that more austenite is converted to martensite after water-quenching than after oil-quenching. The sp. gr., for instance, was smaller after water-quenching than after oil-quenching. H. Scott also noted that an increase in the proportion of austenite was observed by cooling the steel first in oil down to a little above the Ar″-arrest, and then in air to the room temp. K. Heindlhofer and F. L. Wright found that the sp. gr. of steels with 0·55 to 0·71 per cent. of chromium and 0·98 to 1·06 per cent. of carbon was lower with a quenching temp. of 915° to 950° than with a quenching temp. of 800° to 865°. Also oil-quenchings from 865° to 950° gave products with the respective sp. gr. 7·790 and 7·766, while water-quenchings from 800° to 915° gave products with sp. gr. 7·755 and 7·745 respectively.

Various theories attribute the hardening of steel—*vide infra*—to the strains set up on quenching, and consequently some observations have been made on the effects of stress on the decomposition of austenite during quenching. C. Benedicks noticed that austenite is not formed near the surface of quenched specimens heated in graphite to prevent oxidation. During the quenching in liquid air the transformation of austenite to martensite cannot go beyond a certain limit where the increase of press. due to the formation of the specifically lighter martensite would prevent the further transformation of the austenite. If the outer edge of a quenched piece of 1·99 per cent. carbon steel is ground off so as to relieve the stress, the austenite decomposes spontaneously to martensite in a few hours. O. E. Harder and R. L. Dowdell showed that in the drastic quenching of small-sized pieces of metal, when martensite is produced at the edges, the result is probably due to the greater difference in temp. existing between the outside and the centre, which should produce a higher tensional stress. This favours martensite formation because of the increased vol. when martensite forms. During the first stage of quenching the outside of the section must be in tension, which will produce a compression on the inside and tend to retain the austenite by preventing its expansion to martensite. The absence of tensional stress is of more importance in the retention of austenite at room temp. than is the compressive stress. When quenched specimens are martensitic throughout, O. E. Harder and R. L. Dowdell said :

In the first part of the cooling operation the surface must be in tension and the core in compression, but as the cooling continues the tension zone progresses inward. As the outer zone produces martensite of a greater sp. vol. than the austenitic core it should lower the tension and gradually produce compression in the outer zone. The temp. of the core at the time the case changes to martensite on quenching must be considerably higher and as the core cools to ordinary temp. there is a shrinkage due to the normal decrease in vol. with decrease in temp. This must play an important part in producing tension in the core. At this time the outer compressive zone must be balanced by an equal tensional zone in the interior of the specimen which will promote the formation of martensite.

H. V. Wille cut three rings from a quenched steel with 0·41 per cent. of carbon and 0·55 per cent. manganese respectively 0·5, 1·625, and 2·75 ins. from the surface, and found that they were under compression in the original piece, because they expanded when cut off. He estimated that when the forging was quenched in water at 21°, the first ring was under a compression of 42,600 lbs. per sq. in., the

second, 29,500, and the third, 16,500 ; and when quenched in oil, the first ring was under a compression of 42,300 lbs. per sq. in., the second, 16,800, and the third, 4500. Hence the internal stress developed by water-quenching is greater than with oil-quenching. W. Tafel said that owing to thermal changes, if a body of steel be heated to a high temp., the stresses will be small, but if it be quenched, the core, having a greater sp. vol. than the colder shell, will be under compression, while the shell is under tension ; as the interior cools to the same temp. as the shell it will shrink, but since the shell has assumed a greater sp. vol. than normal, owing to the formation of martensite, the stress gradient will reverse, leaving the shell in compression and the core in tension. Observations were also made by T. McL. Jasper, H. Scott, H. J. French and co-workers, G. Tammann and E. Scheil, G. Kurdjumoff and E. Kaminsky, E. Maurer, W. H. Walker, F. Wever, and K. Honda and K. Iwase. Since the transformation of austenite to martensite is attended by an increase in volume, it follows, in accordance with H. le Chatelier's principle (2. 18, 4), that the change will be hindered by compression and favoured by tension. This was established by C. Benedicks, J. Driesen, and E. Scheil. According to E. H. Schulz, the surface layers are cooled more rapidly than the core and more martensite is formed than in the interior. An increase in the sp. vol. attends the transformation of austenite to martensite, and the curve, Fig. 103, showing the decrease in the
Fig. 103. — The Specific Volume at Different Distances from the Surface of a Block of Hard Steel with 1·72 per cent. of Carbon.

sp. vol. as the distance from the surface of a bar of hardened steel increases, shows that the compression in the chilling has hindered the formation of martensite in the interior. O. E. Harder and R. L. Dowdell also observed that when austenite-martensitic steels are tempered under a transverse stress below their yield-point, at temp. between 100° and 200°, a permanent set results ; the bar is longer on the tension side, which indicates that tensional stress favours the change from the γ- to the α-state. No difference in the micro-structure on the tension and compression sides could be detected. The production of martensite from austenite by hammering at room temp. could not be detected, but prominent slip-lines are developed which are characteristically different from martensite needles. Characteristic martensite has been produced from austenite at room temp. by tensile stress. It is very probable that all martensite is formed by a similar process in the normal hardening of tool steels but at a much more sudden and higher tensional stress. An austenitic specimen, which had been previously deformed in tension, was caused to transform to martensite at about −57°, while unstressed specimens were unchanged by this same treatment. An austenitic specimen which had been deformed by hammering decomposed more readily on heating than an unstressed specimen. Deformed austenite is rendered less stable on cooling or on heating.

The cold deformation of austenitic steels was shown by J. H. Hall and G. R. Hanks to favour the transformation to martensite. The Brinell hardness of the surface of a steel with 11·0 per cent. manganese and 1·0 to 1·4 per cent. carbon increased from 190 to 450 during cold-working. The abrasion of the steel produced by sawing also favours the γ- to α-inversion ; and this transformation along the slip-lines of manganese steel was discussed by H. M. Howe. J. H. Whiteley also reported the formation of zig-zag needles of martensite from a high-carbon austenitic steel by impact at room temp. ; and when the needles were tempered at 200°, troostite was formed. E. C. Bain also showed that cold-working greatly favoured the γ- to α-inversion. K. Honda and K. Iwase observed that quenched austenite can be transformed into martensite by cold-working. The internal stresses set up in a steel by quenching promote the transformation of austenite into martensite. Differences in the amount of austenite produced by oil- and water-quenching occur only with thick pieces and can be explained as an effect of internal stress. On

cooling quenched steels in liquid air, the retained austenite is transformed into martensite ; the amount of transformation is less the thinner the specimens.

The decomposition of austenite by tempering.—R. D. Enlund observed that when martensite is tempered at about 100°, there is a considerable decrease in the sp. vol., and when austenite is tempered, there is a large increase in the sp. vol. E. Scheil observed a break at 370° in the cooling curve of austenite corresponding with the formation of martensite. In the formation of martensite by the tempering of austenite, between 150° and 250°, E. Maurer observed that the martensite begins to transform first, but the progress of the change is slower than the transformation of austenite to troostite. H. Hanemann agreed that martensite changes more easily than austenite on tempering. H. Scott and H. G. Movius found that the beginning, maximum, and end of the Ac_0-arrest for a quenched 0·95 per cent. carbon steel are respectively 155°, 250°, and 260°, and that this arrest is raised by increasing the rate of heating. The Ac_0-arrest is the thermal effect observed in tempering quenched steels, and with carbon steels it usually occurs at about 200°. H. Hanemann observed that at 260° to 280° the austenite begins to change to troostite at the already decomposed needles, which act as inoculation centres, and the change then proceeds from the grain boundaries inwards. The carbon content of the crystals of martensite is less than that of the mother austenite. H. S. Rawdon and S. Epstein also noted that the plates of martensite contain a smaller proportion of carbon than the intervening matrix. With steels containing 0·07 to 1·12 per cent. of carbon, quenched between 750° and 1250°, the structural changes are slight when tempered below 250°, but above 250° the martensite and austenite, when present, are transformed, so that the steels assume a granular structure, and react vigorously when etched with dil. acid. No specimen tempered between 100° and 650° showed a scleroscopic hardness greater than the initial hardness produced by quenching. According to H. C. Boynton, the relative hardness of martensite is 2·39 when that of ferrite is unity—*vide infra*, hardness. J. H. Andrew and A. J. K. Honeyman observed that the change of martensite begins at 150°, and is not completed in an hour at 360°. H. von Jüptner gave 7·076 for the sp. gr. of saturated martensite. According to C. Benedicks, the work of F. Osmond, H. le Chatelier, and G. Charpy and L. Grenet shows that the passage from austenite to martensite is accompanied by a considerable increase in volume, and he added that the resulting press. which is developed will prevent the transformation proceeding beyond a certain limit, when the increase of press. corresponding with the increase in vol. will put a stop to the transformation of the γ-crystals. In consequence, these crystals will be preserved as austenite at ordinary temp. H. Scott measured the sp. gr. and hardness of 17·8 per cent. tungsten steels quenched from 900°, 1060°, 1220°, and 1300°, and tempered cumulatively at intervals of 200° for 15 mins. The sp. gr. of specimens quenched above 900° increased to a maximum between 200° and 400°, but specimens quenched at 1220° and 1300° showed a marked decrease on tempering at 600°. Both the scleroscopic and Brinell's hardnesses decreased at about 200°, and rapidly increased to a maximum at 600° ; above 600° the hardness decreased rapidly, probably owing to the coagulation of the carbide. The secondary hardness so developed is due to martensite produced by tempering the austenite. E. C. Bain and Z. Jeffries observed that when a quenched high-speed steel is tempered between 454° and 593°, the passage of austenite to martensite is accompanied by an expansion and an increase in hardness ; while above 593° the growths of ferrite grains and of the iron tungsten carbide particles rapidly produce a softening of the steel as is the case with carbon steels. The stability of the carbon at a red-heat is attributed to the presence of the tungsten atoms which, because of their large size, are prevented from diffusing into the space-lattice of ferrite until the temp. exceeds redness. E. C. Bain found that steels with 1·70 to 2·22 per cent. of carbon and 6·09 to 15·65 per cent. of chromium were quite soft and almost entirely austenitic when quenched from about 1150°, but on tempering at 482° to 593° the steels were martensitized and developed a hardness

nearly equal to that produced by quenching from a lower temp. The tempered specimens did not show the structure of martensite, but rather that of troostite. E. C. Bain added that the cause of the easier retention of austenite in alloy steels is the stronger atomic bonding between unlike atoms which is necessary for any solid soln. Whether or not the product of the change of preserved austenite is martensite depends on the grain-growth in α-iron, and in the carbide. If the carbide precipitation precedes the allotropic change, as is usually the case, the product is very like troostite. O. E. Harder and R. L. Dowdell observed that the decomposition temp. for austenite is always higher than for martensite in the same specimen. The temp. range of the decomposition of austenite is as follows (the first ten results are due to E. C. Bain, and the remaining eight to O. E. Harder and R. L. Dowdell):

Steel	Composition (per cent.)				Range of decomposition
	C	Mn	Cr	W	
Carbon	1·10	0·20	—	—	190° to 250°
Tungsten . . .	1·40	—	0·50	4·0	205° to 280°
Tungsten . . .	2·00	1·30	1·40	1·0	300° to 400°
Oil hardened . .	0·90	1·70	—	—	205° to 287°
Oil hardened . .	0·90	1·20	1·00	—	205° to 270°
Chrome magnet . .	0·85	0·40	2·60	—	205° to 260°
High chrome . . .	1·80	0·35	6·00	—	300° to 535°
High chrome . . .	2·20	0·35	10·00	—	448° to 535°
High-speed . . .	0·70	—	0·40	18·0	538° to 650°
Manganese . . .	1·20	12·00	—	—	413° to 620°
High nickel (graphitized) .	0·99	0·04	—	22·57 (Ni)	625° to 670°
Cobalt-chromium . .	0·86	0·13	9·31	13·66 (Co)	525° to 562°
High manganese . .	1·37	11·88	—	—	410° to 480°
Chromium . . .	2·22	0·36	10·56	—	150° to 200°
High-speed . . .	0·76	0·07	4·38	20·0	150° to 200°
High carbon . . .	1·35	0·24	—	—	150° to 200°
Tungsten . . .	1·37	0·20	0·56	5·91	150° to 200°
High carbon . . .	2·66	0·22	—	—	150° to 200°

E. S. Davenport and E. C. Bain found that the transformation of austenite is most rapid at 540°, and in the range between the Ac_1-arrest and 500° the rate decreases with either increasing or decreasing carbon content as the eutectoid recedes. The presence of chromium or of manganese retards the transformation. At lower temp. both manganese and carbon decrease the rate of transformation. The decomposition of austenite during tempering was found by H. S. van Vleet and C. Upthegrove to follow the austenite→martensite→troostite→sorbite type of change, but at the temp. of liquid air the decomposition follows the austenite→ troostite type of change without the accompanying growth of cementite and ferrite.

O. E. Harder and R. L. Dowdell observed that with carbon steels the martensite needles, which are light-coloured and in relief, progressively darken at 100° as time increases, and the sp. gr. show that the precipitation of carbide particles takes place slowly until dark troostite is formed. The tempering at a higher temp., 200° to 270°, is attended by a coarsening of the structure, and this is followed by a decrease in hardness, probably caused by grain-growth in the ferrite, and the coalescence of the carbide to a size that can be recognized as a distinct phase. In alloy steels the martensite decomposes on tempering as in the case of carbon steels, the martensite needles darken, but they are more stable in alloy steels and require for their decomposition a higher temp. or a longer time, or both. Martensite needles can be produced by tempering chromium and manganese steels. It is possible that there is an overlapping of the ranges of stability of the austenite and the martensite of steels of certain compositions. Frequently dark needles (troostite) are produced in the tempering of austenitic steels. Nodular troostite usually forms on tempering austenite. Its common places of formation are at grain boundaries, along slip-planes, or along martensite, cementite, or troostite patches.

H. J. French and co-workers found that a high-speed steel—with 0·56 per cent. carbon ; 2·21, chromium ; 13·80, tungsten ; and 0·98, vanadium—quenched from about 1260° in oil, and in an air blast, and tempered cumulatively at intervals of about 93°, had a minimum contraction of approximately 0·0002 in. in 4 ins. at 482°, and it then rapidly expanded when tempered at about 593°. M. A. Grossmann and E. C. Bain observed that a tungsten steel—with 1·08 per cent. carbon ; 0·35, manganese ; 0·36, silicon ; 2·66, tungsten ; 0·50, chromium ; and 0·29, vanadium—quenched in oil from 871°, 927°, 982°, 1093°, and 1204°, underwent a maximum contraction at about 127°, a maximum expansion at about 260°, and a contraction at 649°. H. Scott obtained analogous results with a steel containing 1·10 per cent. of carbon and 1·10 per cent. of chromium. The ageing of the steel for an hour at 100° produced the same contraction as a natural ageing for six months. A maximum contraction occurred on tempering for an hour at 150° to 200° ; a maximum expansion at 260° ; and on tempering at higher temp., a continuous contraction occurred until the value for annealed steel was obtained. With a higher quenching temp., or with an oil-quenching to near the Ar″-arrest and then cooling in air, the initial contraction is lowered and the expansion at 260° is raised. This shows that more austenite is retained by oil-quenching owing to the development of a press. sufficient to retard the transformation at an earlier stage with slow cooling than with fast cooling because of the shrinkage of the matrix of martensite produced by the transient tempering which occurs when the metal is slowly cooled through the Ar″-arrest.

E. Maurer, and O. E. Harder observed that in the tempering of 0·70 to 1·18 per cent. carbon steels there is a rapid decrease of the remanent magnetic induction at about 100°, there is a break in the curve at about 260°, a maximum at about 500°, and subsequently a decrease at a slower rate. The results agree with observations on the sp. gr., changes in vol., and coercive force. The decrease in the remanent magnetic induction and tempering is attributed to the tempering of martensite, and the increase, to the α-iron formed in the tempering of the austenite. K. Heindlhofer and F. L. Wright observed two transformations in the tempering of quenched steels with a low proportion of chromium : (i) a transformation from a specifically light form to a denser form is attributed to a break-down of the martensite which proceeds over a wide range of temp. ; and (ii) a transformation from a specifically dense form to a lighter form occurring over a narrow range of temp., 200° to 260°, and attributed to the retained austenite changing to martensite. This was confirmed by the dilation curves of H. Styri. B. D. Enlund found that with carbon steels with between 0·21 and 1·57 per cent. of carbon, and tempered at various temp., the electrode potentials show that martensite is transformed into troostite at 100° to 200°, but the reaction is most marked at 110° ; that austenite is decomposed at about 260°, and at 270° the microstructure of the high-carbon steels is wholly troostitic. Even low-carbon steels retain a considerable proportion of austenite when quenched from ordinary quenching temp. The transformation of austenite was also discussed by A. M. Portevin and P. Chevenard, E. S. Davenport and E. C. Bain, N. Engel, and W. Brenscheidt. According to E. Walldow, the transformation of α-iron to γ-iron starts at the grain boundaries. U. Dehlinger studied the effect of grain-size on the rate of transformation.

O. E. Harder and R. L. Dowdell found that the austenite of different steels quenched and later submerged in liquid oxygen exhibits different stabilities.

The transformation to martensite is practically complete with plain carbon steels, while in the case of manganese and some high-speed steels little or no martensite is formed. The microstructures of martensite produced by ordinary quenching and by cooling with liquid oxygen are similar—white needles with a midrib structure when the orientation is suitable. The greater proportion of martensite produced at the interior than at the surface is attributed to the production of a compression on the outside and a tension on the inside, in which case the tensional stress favours the phase of greater vols.—that is, the martensite. The decomposition of austenite at liquid oxygen temp. is a recrystallization phenomenon which shows itself first along slip-planes, and is accompanied by an increase

in hardness and decrease in sp. gr. In agreement with F. Osmond, and H. Hanemann, the formation of martensite from austenite in liquid oxygen probably takes place rapidly and almost immediately after immersion. However, this rate may be somewhat slower than when it forms on commercial quenching, owing to the decrease in the atomic mobility at the much lower temperature. Finally, the reaction does not go to completion, which may be influenced by the greater volume of the martensite which may relieve tensile stress and even produce compressive stress. The less stable structures, as in the carbon steels, go more nearly to completion. This is shown by the microstructures after long periods of time and by the changes in hardness.

E. Scheil showed that the change from austenite to martensite is favoured by tensile stresses and hindered by compressive stresses. The transformation of residual austenite which occurs below 0° is exposed to tensile stresses owing to the difference in the coeff. of expansion of austenite and martensite.

J. O. Arnold assumed that the Ar_1-arrest is connected with the formation and dissociation of an unstable carbide, $Fe_{24}C$, of intense hardness, and accordingly he called it **hardenite.** The microscopic appearance of hardenite in a specimen of hardened tool steel is shown in Fig. 104. The microstructure sometimes shows no sign of crystallization. Hardenite is said to be the unsegregated eutectoid with its 0·8 to 0·9 per cent. of carbon, and, when annealed, it furnishes 100 per cent. pearlite, or $21Fe + Fe_3C$—J. O. Arnold called the product *true steel*. If J. O. Arnold meant that the eutectoid is a chemical individual, he reverted to the old cryohydrate theory which regarded eutectics as chemical compounds. In that case, hardenite is $Fe_3C.21Fe$, or cementite with " iron of crystallization." F. Osmond believed that hardenite is a saturated martensite which has a mesial rib that etches more deeply than the other parts. Martensite is not normally stable at any temp., and can be preserved in this unstable state only at comparatively low temp.—*vide infra,* tempering. For a steel of a given composition, it is distinguished from austenite by its greater magnetic permeability, and hardness. H. C. H. Carpenter and C. A. Edwards suggested as an hypothesis that martensite and austenite are constitutionally identical, and differ only in the repeatedly twinned structure of the martensite. C. H. Desch believed that the difference is more profound than is implied by this hypothesis. The subject was discussed by C. Benedicks and E. Walldow, H. Hanemann and J. H. Wiester, S. Steinberg, and M. Matweieff.

FIG. 104.—Structure of Hardenite (E. Heyn).

Martensite is sometimes considered to be responsible for the hardness of quenched carbon steels—*vide infra,* theories of hardening. According to W. Rosenhain, the alleged hardness of acicular martensite may be illusory, in that the hardness of such a structure is accidental rather than causative. The acicular martensite is not necessarily hard. Thus, steels of low carbon content, which undergo no appreciable degree of hardening when quenched, often show a well-developed martensite structure. It is possible that the acicular structure of martensite is associated primarily with the allotropic transformation of iron, and not with the hardening process itself.

Martensite is a solid soln. of carbon or iron carbide in iron—F. Osmond said that iron is partly in the α- and partly in the β-state ; H. le Chatelier, in the α-state ; and C. Benedicks, in the β-state ; but later he stated that what was formerly regarded as β-iron is a soln. of α- in γ-iron ; and added that the soln. is supersaturated, but not undercooled. Z. Jeffries and R. S. Archer believe that martensite consists of

fine-grained a-iron in which carbon is atomically dispersed in the lattice of a-iron as a kind of supersaturated soln., for carbon is considered to be soluble in γ-iron, but almost insoluble in a-iron. Equilibrium is established by the precipitation of carbon. Under favourable conditions the martensite slowly changes and cementite is formed: $3Fe+C=Fe_3C$—vide infra, the hardening of steel. R. Ruer said that martensite is not a true soln. of carbon or cementite in a-iron. E. Maurer's hypothesis that martensite is a supersaturated soln. of carbon in a-iron was confirmed by E. Oehman.

J. O. Arnold argued that martensite is really structureless hardenite, $Fe_{24}C$; but this is rather a question of nomenclature. The term martensite usually refers to needle-like, microscopic structures, characteristic of quenched steels, which appear to be formed on the two sides of the incipient, octahedral cleavage planes of austenite. The structure of martensite is sometimes very like that of austenite, but it more frequently shows characteristic acicular markings, or interlacing needles, Fig. 105. This diagram represents a steel with 1·54 per cent. carbon heated for 15 mins. at 1350°, and then quenched in water at —5°. It has been etched with picric acid. It shows the needles of martensite in a matrix of austenite. F. Osmond observed that when etched, martensite is whiter than the matrix of austenite, which

FIGS. 105 and 106.—Martensite in a Matrix of Austenite (Fig. 106, after F. F. Lucas).

usually etches a yellowish tint. C. Benedicks also said that the natural colour of the acicular or lanceolate martensite is slightly darker than when polished, and if the specimen be allowed to stand in air, the austenite rusts before the martensite is affected. Fig. 106 ($\times 2100$) represents martensite in austenite in a steel with 2·65 per cent. carbon and 0·07 per cent. manganese; and etched with picric acid. Photographs of high magnification were also made by R. A. Hadfield and T. G. Elliott. H. Hanemann said that the martensite in steel, unlike austenite, is anisotropic. F. Osmond said that the martensitic structure appears to have three systems of fibres arranged parallel to the three sides of a triangle and crossing each other frequently, imparting the fer de lance structure; the needle-like crystals assume various other forms—vide Figs. 105 and 106; and vide infra, Neumann's bands. The structure of martensite was discussed by A. Allison, K. Heindlhofer and E. C. Bain, and others—vide infra. F. Osmond and G. Cartaud refer to them as pseudomorphs of twinnings due to tension occurring in γ-iron, through the partial formation of the bulky β- and a-allotropes of iron. According to H. C. H. Carpenter and C. A. Edwards, the acicular markings of martensite are due to the twinning of the crystals of the solid soln. of carbon and γ-iron by the strains set up in the process of quenching—vide infra, Neumann's bands. J. E. Stead added that if martensite is twinned austenite the zigzag portions of what is considered to be martensite in

austenite would not be of the same light or dark tint in any given microscopic field. They are always either all light on a dark ground or dark on a light ground, according to the method used in etching. When the zigzag structure is large enough to be examined under oblique light, there is no change in the appearance of the martensite during the rotation of the specimen. The magnetic properties and hardness do not increase with the proportion of martensite. *Ergo*, martensite is not twinned austenite, but is an independent substance. According to O. E. Harder and R. L. Dowdell, the so-called needles of martensite in a ground-mass of austenite, produced by the quenching of austenitic steels, are really plates formed by the octahedral slip-planes of the austenite, and they appear on a polished and etched surface either as narrow or wide plates which frequently form with one another an angle of 60° or 120° If the carbon steel has about 1·7 per cent. of carbon, and is quenched from about 1100°, the steel, at room temp., will contain roughly equal amounts of austenite and martensite, and the ground-mass will be the austenite. F. Sauerwald and co-workers found that the martensitic structure of steel is always oriented in the same way as the original grain boundaries, and that the slip-planes are similarly oriented. It is therefore assumed that the acicular structure of martensite is caused by slip phenomena induced by the hardening or quenching process ; it is also assumed that martensite is not a distinctive phase in the structure of steel.

F. F. Lucas inferred that a martensite needle is a decomposition product which first appears along the octahedral crystallographic planes of austenite, and it is confined to an area of uniformly oriented austenite, *i.e.* a needle never crosses a grain boundary or a twinning plane. Martensite needles darken with sodium picrate, an etching soln. which selects iron carbide. They also etch with nitric or picric acid, a reagent which does not stain or attack the carbide. Martensite needles have a mottled, granular appearance, and often a line structure is found, whilst occasionally needles are found which exhibit multiple twinning. A martensite needle is an aggregate and not a solid soln., and it indicates a decomposition of the austenite probably to α-iron and iron carbide highly dispersed. Later observations, taking precautions to prevent tempering during the preparation of the specimens, show that instead of the needles being mottled uniformly over the entire surface, they are either white or exhibit a delicate line structure traceable to the octahedral planes. Under high powers, avoiding surface tempering, the quenched steel does not give a felted mass of brown needles when the specimens are etched in the usual way, rather are the needles white, and it is the matrix in the interspaces between the needles which etches or dissolves away, so that the needle-like forms are more resistant to etching than the matrix in which they are found. Some needles are slightly mottled and some occasionally turn brown before the interspaces begin to develop. The white needles readily turn brown on tempering and develop a mottled structure, *i.e.* they start to precipitate carbide.

According to F. F. Lucas, and A. Sauveur, therefore, the needles of martensite are not made up of a single phase, but appear to be aggregates. The needles have a central mid-rib which is darker than the surrounding metal—Fig. 106. The mid-rib is supposed to be made up of troostite resulting from the transformation of austenite along its octahedral cleavage ; and the remainder of the needles is supposed to contain some troostite in a state too finely divided to be detected microscopically, but in sufficient quantity to darken the colour of the needles. A. Sauveur thus regarded martensite as an aggregate of solid soln. of iron carbide in γ-iron and of iron carbide in β-iron. An analogous hypothesis is held by H. C. Boynton, J. H. Andrew, L. Grenet, F. F. Lucas, and H. H. Lester. Here, the cooling of the austenite results in the more or less incomplete transformation of the iron into the β-state (A. Sauveur) or into the α-state (F. F. Lucas, and H. H. Lester). The austenite that is transformed becomes troostite, so that martensite is considered to be a mixture of retained austenite and troostite. A. Sauveur considers that troostite is first precipitated from the austenite. The troostite is unstable, and it

may be α-iron with carbide in solid soln., or it may be an atomic aggregate of the two. He said that martensite is an aggregate of undercooled austenite and a supersaturated soln. of carbon in α-iron ; that the mechanism of the transformation of austenite to martensite is independent of the rate of cooling ; and that the change is brought about by an α-phase starting around the grain boundaries and along some of the crystallographic planes of the mother austenite ; this gives rise to a Widmanstätten structure on slow cooling, and a martensitic structure on rapid cooling. H. H. Lester regarded martensite as an aggregate of small distorted crystals of iron or of a solid soln. of iron and carbon. F. F. Lucas regarded martensite as an aggregate of ferrite or α-iron and cementite. H. Esser and W. Eilender likewise concluded that martensite is a heterogeneous mixture of α-iron and cementite, and not a solid soln. K. P. Grigorovich considered that the needle-like appearance and the zig-zag lines of martensite are optical effects produced by internal stresses. J. H. Andrew, and L. Grenet also considered martensite to be finely-divided cementite suspended in a matrix of undecomposed austenite and α-iron. Starting with steel in the austenitic condition, with all the carbides absorbed, on quenching quickly white needles are formed comprising a large proportion of the structure. J. A. Mathews, E. C. Bain, and B. D. Enlund have shown that some steels then consist of a mixture of (i) untransformed γ-iron, the original matrix ; (ii) iron carbide, which is formed as the γ-iron changes to α-iron ; and (iii) α-iron. J. Orland concluded that martensite is not a solid soln. of α-iron and carbon, but it occurs in at least two phases distinguishable by etching with nitric acid. K. Gebhard and co-workers also concluded that martensite contains two phases. The heterogeneity and structure of martensite were discussed by E. Oehman, and E. Maurer and G. Riedrich.

Z. Jeffries and R. S. Archer, E. C. Bain, C. Benedicks, P. Chévenard, A. M. Portevin, W. H. Hatfield, K. Honda, A. McCance, and O. E. Harder and R. L. Dowdell consider that when austenite, a solid soln. of carbon or iron carbide in γ-iron, is rapidly cooled, more or less γ-iron is transformed into α-iron, and carbon or iron carbide remains in a kind of supersaturated solid soln. K. Honda and K. Iwase assume that martensite is the first stage in the transformation of a solid soln. of carbon in γ-iron, and it is merely a solid soln. of carbon in α-iron. The solubility of carbon in α-iron is small, so that by rapid cooling the change is equivalent to the production of a supersaturated soln. Austenitic steels, as indicated below, can be converted at room temp. into martensitic steels by tensile stress, by hammering, and by the stresses set up when plunged into liquid air. K. Schröter showed by magnetic observations that the transformation occurs during the cooling and not during the subsequent restoration to ordinary temp. ; and A. Sauveur, and A. Sauveur and C. H. Chou, that when the γ-phase is converted into the α-phase by quenching, the α-phase first appears along the crystallographic planes of austenite and around the boundaries of the grains. According to K. Honda and K. Iwase, freshly-formed martensite hardens on standing for several hours at ordinary temp., or for a few minutes at 100°, so that a temp. in the vicinity of 0° is necessary to prevent the ageing or hardening of martensite. Otherwise expressed, the ordinary temp. of a room is near the limit which will permit the diffusion of carbon in steel, and at any lower temp. the austenite can be held indefinitely in a frozen, torpid condition. The formation of cementite is accompanied by a contraction, and the change from γ-iron to α-iron, by an expansion. The formation of martensite is attended by an expansion, so that, as emphasized by Z. Jeffries, the principal change involves the transformation of γ- to α-iron, and not the production of carbide. In the reheating of martensite the contraction which occurs is due to the formation of cementite. The austenitic, supercooled, solid soln. in γ-iron is unstable, but, at room temp., it changes only slowly into a solid soln. in α-iron. The solid soln. at room temp. is supersaturated with respect to either carbon or cementite, but the thermal agitation of the atoms is too slow to permit a rapid splitting of the martensite into its constituents. It is not clear whether carbon or cementite is the first stage of this transformation where troostite (*vide infra*) is formed.

Ageing or a slight tempering either causes a slight coagulation of the iron carbide into larger particles or else it results in a diffusion of the carbon atoms which form iron carbide, and on further tempering the iron carbide commences to coagulate. The very fine particles of carbide precipitated from the austenite during the quenching may be too minute to be visible microscopically. This is white martensite. With even a slight tempering the fine particles grow to microscopic dimensions. Z. Jeffries assumes that granules of α-iron are intimately associated with the white martensite ; the granules may or may not have carbide in solid soln. C. Benedicks said that there is not a single cause for assuming that martensite and austenite have a different empirical structure ; the difference in their properties on etching, etc., must be attributed to the different states of iron—γ-iron in austenite and β- or rather α-iron in martensite ; austenite is a supercooled solid soln., martensite, a supersaturated solid soln.

A. Westgren and co-workers found that the space-lattice of the iron in martensite corresponds with that of α-iron, and this is also the case with high-speed steel of ordinary composition and hardened at 1275°. A 1·98 per cent. carbon steel quenched in water from 1000° or 1100° had a lattice parameter $a=2·90$ A., and when quenched from 760°, $a=2·88$ A., indicating that the martensite contained α-iron. A 1·25 per cent. carbon steel, quenched in water from 760°, had $a=2·88$ A., indicating that the lattice parameter depends on the amount of carbon in soln. and the quenching temp. When austenitic manganese and nickel steels were immersed in liquid oxygen, the manganese steel showed no change in the X-radiogram, but the nickel steel was changed so that the γ-lines still existed, but they were not sharp but diffuse, indicating that the steel had become extremely fine in crystalline structure ; the lattice parameter of the α-iron produced by this treatment had $a=2·81$ A., while that of the γ-iron changed from 3·58 to 3·54 A. Only half the original austenitic structure was then changed to white, lanceolar needles. K. Heindlhofer also found that martensite has a body-centred cubic lattice-like α-iron, and inferred that it is spaced approximately 0·4 per cent. closer than the lattice of α-iron. Martensitic steel with 0·80 per cent. of carbon shows the same X-ray spectral lines as iron alone, but the lines are less intense, somewhat broader, and slightly shifted, the amount of shift being approximately the same for different carbon contents. The sp. gr. data show that a considerable part of the carbon present in martensite replaces iron atoms in the space-lattice. The carbon atoms are in the proportion 5 : 9 smaller in diameter than the iron atoms which they replace, and this causes considerable lattice distortion. In general, the results indicate that martensite is a mixture of two constituents, present in variable proportions ; one is a solid soln. of carbon in α-iron and the other is finely dispersed cementite. The solid soln. is unstable and some of the carbon gradually separates from the lattice even at room temp., so that it is difficult to keep more than a part of carbon in soln. Consequently, while austenite is a structure in which a face-centred cubic lattice of iron atoms also has carbon atoms in the interstices, martensite is a structure with a body-centred cubic lattice of iron atoms with carbon atoms in the interstices, as the iron in austenite passes from the γ- to the α-state when it is cooled below the Ac_1-arrest. The X-radiograms show that in addition to α-iron, some lines of γ-iron are always present in martensite, indicating that the transformation of the austenite is not complete. The unconverted austenite is called *retained austenite*. The solid soln. is unstable even at the ordinary temp. At 260° the lattice distortion of martensite largely disappears in 30 minutes, although only part of the carbon is precipitated, and the hardness is still far above that of the annealed state. The cementite also contributes to the hardness by reason of its fine-grained condition. R. F. Mehl and co-workers' observations on compressibility also agree with the assumption that martensite consists largely of ferrite and finely-divided cementite. J. Orland, and K. Gebhard and co-workers also agree that martensite consists of two phases involving a metastable system. W. Broniewsky regarded martensite as a transitional substance not deserving a place in the equilibrium

diagram of the iron-carbon alloys. S. Sekito studied the conversion of martensite to cementite (*q.v.*).

W. L. Fink and E. D. Campbell reported that in strongly-quenched, eutectoidal and hypereutectoidal carbon steels, the crystal structure seems to have a body-centred tetragonal lattice with $a=2 \cdot 85$ A., and $c=3 \cdot 02$ A., or an axial ratio $a : c$ $=1 : 1 \cdot 06$, so that the a-axis increased from 2·55 to 2·85 A., while the c-axis decreased from 3·60 to 3·02 A. E. C. Bain, however, showed that in changing from the γ- to the a-lattice, the body-centred arrangement is at first tetragonal with an axial ratio $a : c = 1 : 1 \cdot 414$; and suggested that the final condition in martensite is an incomplete transformation to the " perfectly cubically crystallized a-iron."

Z. Jeffries and R. S. Archer said that when the cooling rate of austenite is rapid enough to form martensite, the transformation of the γ-iron to a-iron is substantially complete, while the formation of cementite is not complete. Martensite therefore consists principally of submicroscopic a-iron or ferrite grains containing carbon in soln. The carbon of the mother austenite will strive to precipitate as particles of cementite, and the extent of the reaction will depend on the conditions of temperature and time during quenching, ageing, and tempering. That the formation of martensite from austenite represents a change from γ- to a-iron is shown by : (i) the complete change in the microstructure of martensite, as compared with that observed when austenite is preserved by quenching, indicates a transformation of the γ-iron ; (ii) the magnetic susceptibility of martensite suggests the presence of a-iron ; and (iii) the X-radiograms show that a-iron is the principal constituent of martensite. Non-magnetic steels have face-centred cubic lattices characteristic of γ-iron, whereas magnetic, martensitic steels have the body-centred cubic lattice characteristic of a-iron. A 1·5 per cent. carbon steel quenched in iced brine from above the critical point has both martensite and austenite and both body-centred and face-centred cubic lattices, whereas a 0·35 per cent. carbon steel quenched from above the Ac_1-arrest shows the presence of martensite only and only the body-centred lattice. K. Heindlhofer and E. C. Bain observed that martensite is composed of characteristically distorted ferrite units or grains, not markedly different in size from those of the parent austenite. The type of distortion is that developed by twisting or bending, so as to retain a moderate constancy of spacing between the (110)-planes, but at the same time to vary the orientation of some of the same planes through a considerable angle. The ferrite units possess a marked random atomic irregularity of the solid soln. type—*vide infra*.

K. Honda, T. Matsushita, S. Sato, and K. Honda and S. Sekito showed that there are probably two martensites—a-**martensite,** which has a body-centred tetragonal lattice, with the axial ratio $c : a = 1 \cdot 03$ to 1·06, is formed from austenite when the cooling is rapid ; and β-**martensite,** which has a body-centred cubic lattice. When steel is quenched, the change of austenite to a-martensite is partly arrested and the change of a-martensite to β-martensite is completely hindered, so that in the outer layer, where the cooling is rapid, a-martensite with a little austenite is present ; but in the inner portion, where the cooling is slower, both changes occur almost completely, and β-martensite alone is found there—*vide infra*, hardening. T. Matsushita, H. Hanemann and A. Schräder, and K. Honda showed that during the slow heating of a quenched high-carbon steel the heating curves indicate that the separation of carbon in the form of cementite occurs in two stages, one at 130° and the other at 280°. This is taken to mean that there is an a-martensite and a β-martensite distinguishable by their degree of tempering. Later K. Honda showed that it is more probable that the 130° breaks in the curves of magnetization, heating, electrical resistance and thermal expansion are not caused by the decomposition of martensite by the precipitation of cementite, but rather by the change of a- into β-martensite. The change at 130° begins at about 100°, is very rapid at 230°, and is completed at 300°. M. A. Grossmann found that a high-speed steel, quenched from a high temp., was softer when tempered at 482° than at 593°, and the result was explained on the basis of the a- and β-martensites.

T. Matsushita, and K. Honda attributed the hardness of quenched steels to the presence of β-martensite, not a-martensite. a-martensite is first formed in a cooling austenitic steel, and then β-martensite. The changes are reversed on heating pearlitic steels. The a-martensite is more easily etched by picric acid and more easily tempered by heating than β-martensite. W. L. Fink and E. D. Campbell, and N. Seljakoff and co-workers observed that in addition to the body-centred cubic lattice in quenched carbon steels there is also a body-centred tetragonal lattice with the axial ratio $c : a$ approximating 1·06. K. Honda and S. Sekito consider that the body-centred cubic lattice represents ordinary or β-martensite, and the body-centred tetragonal lattice, a-martensite—*vide infra*, ferrite, and also hardening. K. Honda and S. Sekito found that the parameter of the body-centred cubic lattice of β-martensite is lengthened with increasing proportions of carbon, thus :

Carbon	.	0·202	0·396	0·508	0·620	0·730	0·895	1·04 per cent.
A	. .	2·860	2·863	2·864	2·864	2·867	2·870	2·866
Sp. vol.	.	0·1271	0·1275	0·1276	0·1276	0·1280	0·1284	0·1279

whilst for a-martensite with its body-centred tetragonal lattice :

Carbon	.	0·202	0·396	0·508	0·620	0·730	0·895	1·04	1·075 per cent.
A	. .	2·839	2·838	2·836	2·832	2·834	2·837	2·838	2·839
$c : a$	.	1·068	1·073	1·072	1·073	1·072	1·066	1·066	1·055
Sp. vol.	.	0·1327	0·1332	0·1327	0·1324	0·1324	0·1321	0·1323	0·1313

A face-centred cubic lattice can be regarded as a body-centred tetragonal lattice with the axial ratio $c : a = \sqrt{2}$ (Fig. 107); and a body-centred cubic lattice as a body-centred tetragonal lattice with the axial ratio $c : a = 1$. Observations show that the axial ratio of the body-centred tetragonal lattice of a-martensite has the axial ratio $c : a = 1\cdot03$ to 1·06. The alterations in the tetragonal lattices involve the change from austenite ($c : a = \sqrt{2}$) to a-martensite ($c : a = 1\cdot03$ to 1·06) and to β-martensite ($c : a = 1$). The successive changes involved in the transformation of the face-centred cubic lattice of austenite to the face-centred tetragonal lattice involve a uniform compression in the direction of the c-axis of the tetragonal lattice with $c : a = \sqrt{2}$, and at the same time a uniform expansion in a perpendicular direction ; when $c : a = \sqrt{2}$ has changed to 1·03 to 1·06, a-martensite is formed, and as the change continues until the ratio is unity, ordinary or β-martensite with its body-centred cubic lattice is formed. The fact that in martensite two tetragonal configurations (with $c : a = 1\cdot06$ and 1) of the iron and carbon atoms are possible can be explained by the electron theory of atomic structure. The actual form of the atoms is far from being spherical, and hence it is quite probable that the orientation of the carbon atoms in relation to the iron atoms in the lattice may give rise to two or more metastable configurations. In the outer layer of a quenched steel, where the cooling is very rapid, the first change of austenite to a-martensite goes on partially, and the second change of a-martensite to β-martensite is completely hindered, so that the outer layer must contain a-martensite mixed with a small amount of retained austenite ; while in the inner portion, where the cooling is less rapid, the first and the second changes will take place almost completely, so that the inner portion must contain almost pure β-martensite. The general result for single crystals was confirmed by G. Kurdjumoff and G. Sachs. The length of the c-axis increases, whilst that of the a-axis diminishes, with increasing carbon content. In a steel containing 1·03 per cent. C the ratio c/a is constant (1·041 to 1·045) for initial temp. of 900°, 1100°, and 1300° ; in a steel containing 0·91 per cent. C the diminution of the ratio commences at 850°. The non-homogeneity of the tetragonal structure causes diffusibility of the lines of the X-radiograms. K. Honda's β-martensite is probably a mixture of tetragonal crystals with different small ratios of the axes.

FIG. 107.—The Relationship of the Face-centred Cubic Lattice to the Body-centred Tetragonal Lattice.

G. Kurdjumoff and E. Kaminsky found that in quenched steels containing 0·64 to 1·44 per cent. of carbon, the tetragonal structure exists not only at the surface, but also at a depth of 5 mm. G. Kurdjumoff and co-workers found that the mixture of austenite and martensite in a chilled 1·5 per cent. carbon steel had the (011)-plane of the tetragonal crystallites parallel to the (111)-planes of austenite,

and the (111)-direction to the (101)-direction giving an 8° angle between the tetragonal and the austenite axis. This position repeats itself 24-fold in agreement with the general cubical symmetry; and it can be derived from a superposition of two simple slip motions. E. Oehman measured the (101)-line in the X-radiogram of the tetragonal phase, and obtained the results indicated in Table XI for the linear dimensions of the tetragonal lattice in A-units and for the vol. per lattice point in A_3-units; similarly also for the face-centred lattice of γ-iron. The results are plotted in Fig. 108, and show the convergence of the curves for the axial dimensions converge to a point corresponding with the edge of the elementary cube of α-iron. This is in agreement with the results of G. Kurdjumoff and E. Kaminsky, and with their assumption, confirmed by the thermal observations of E. Maurer and G. Riedrich, and the microscopic observations of F. Wever and N. Engel, that tetragonal martensite is a supersaturated soln. of carbon in α-iron; and that tetragonal martensite and ferrite are one and the same phase.

FIG. 108.—The Lattice Dimensions of the α'-Phase, and the Volumes per Lattice Point of the α'- and γ-Phases.

The two may be present in one specimen, and hence E. Oehman designates the tetragonal phase as the α'-phase.

Three hypotheses are available as to the disposition of the carbon atoms in the α'-phase. (i) According to A. Westgren and G. Phragmen, the carbon atoms dissolved in γ-iron do not occupy points of the face-centred lattice, but are statistically distributed in the interstices between the iron atoms. N. Seljakoff and co-workers suggested a similar arrangement for the α'-phase, and in order to explain the tetragonal deformation assumed that the carbon atoms are distributed at the centre of those faces which are perpendicular to the tetragonal axis. E. Oehman added that this arrangement is improbable, since the space available for the carbon is very small, and even if a carbon atom were located at one of the points where the distances to the surrounding iron atoms are greatest, the space available for the carbon atom would be much smaller than in the face-centred structure; and as a consequence, the vol. of the body-centred lattice would increase more rapidly with the carbon content than would be the case with the face-centred

lattice. The curves for the α'- and γ-phrases, Fig. 108, show that the converse of this inference is true. (ii) G. Hägg suggested that the carbon atoms may be so disposed that two carbon atoms replace one iron atom in the lattice, as was observed by M. von Stackelberg for many tetragonal carbides, and analogous with the tetragonal lattices of some hydrides observed by G. Hägg, where two hydrogen atoms occupy the place of one metal atom. It is further assumed that the C_2-groups are oriented parallel with the tetragonal axis of martensite. (iii) E. Oehman suggested that the carbon atoms are simply substituted for iron atoms in the lattice, and this explains the decrease in the lattice dimensions, since the carbon atoms are much smaller than the iron atoms.

E. Oehman found that when the α'- or tetragonal phase is produced by quenching steel containing 1·35 per cent. of carbon and allowing it to remain in liquid air for 48 hrs. the sp.gr.was 7·62. The specimen contains both γ-iron and α'-iron, with the latter predominant. The sp. gr. of austenite with 1·34 per cent. of carbon is 7·94 ; the sp. gr. of α'-iron (i) with interstitial carbon atoms is 7·65 ; (ii) with a substitution of doubled carbon atoms, 7·42 ; and (iii) with a substitution of single carbon atoms, 7·19. The observed sp. gr. does not agree with (i) ; the observed sp. gr. would agree with 60 per cent. of α'-iron and 40 per cent. of γ-iron, which is in harmony with (ii) ; and the observed sp. gr. requires 57 per cent. of γ-iron and 43 per cent. of α-iron if the third assumption be valid, but this is not in conformity with the intensities of the X-ray lines, which show that the α'-phase is dominant. Hence the only structure in agreement with the observed sp. gr., the increase in vol. with the carbon content, and the elongation of one of the crystallographic axes is that in the body-centred lattice C_2-groups of carbon atoms replace some iron atoms. The carbon atoms are probably oriented in such a way that the axes of the C_2-groups are parallel to the tetragonal axis of the lattice. The α'-phase is decomposed on tempering.

The sp. gr. of α-martensite is less than that of β-martensite. The sp. vol. of α-martensite is represented by $v=0·1335-0·0018[C]$, and that of β-martensite by $v=0·1267+0·0017[C]$, where [C] denotes the percentage of carbon. The carbon atoms of β-martensite are assumed to be distributed in the centre of the face of the elementary cube, in accord with the laws of probability. The atomic distances in α-martensite are a little greater than in β-martensite, in agreement with the greater hardness of β-martensite. S. Sekito found that the axial ratio of the tetragonal lattice diminishes in magnitude from the surface to the interior, finally taking the value unity. The axial ratio of the tetragonal lattice increases with the carbon content, as well as with the quenching temp.

The changes in the space-lattice which occur during the transformation of austenite into martensite were also discussed by A. E. van Arkel, S. Sato, K. Becker, O. E. Harder and R. L. Dowdell, F. C. Elder, U. Dehlinger, E. Scheil, G. Tammann and A. Heinzel, O. Mügge, K. Honda, A. Westgren, F. Wever, and A. Smekal. F. Wever represented the effect of carbon and manganese in austenitic steels on the parameter of the iron lattice by $3·578+0·0005[Mn]+0·00645[C]$, where the bracketed symbols represent atomic percentages. The lattice parameter of α-iron is increased from 2·861 A. to 2·875 A. in hardened steel, but is practically unchanged in annealed steels. Hence carbon atoms fill spaces in the lattice of α-iron, and do not replace iron in the lattice structure. The space-lattices are discussed below in connection with ferrite, and also in connection with hardening. The marked broadening of the diffusion of the X-ray spectral lines of the martensites was explained by A. Westgren by assuming that each individual martensite crystal consists further of a very large number of minute crystals oriented at random, their linear dimensions containing only several hundreds of atoms. K. Honda and S. Sekito said that this does not agree with the fact that martensite consists of well-defined acicular crystals, and they attributed the phenomenon to a continuously varying strain of the iron lattice caused by the carbon atoms in the interspaces. N. Seljakoff and co-workers do not accept the inference that the axis of the lattice of tetragonal martensite is independent of the carbon content ; the

presence of carbon atoms in the lattice produces a decrease in the intensity, but not a broadening, of the spectral lines.

Both martensite and austenite are supposed to be unstable, and with a prolonged annealing their transformation into the stable phase will proceed to an end. The mechanism of tempering has been studied from different points of view—changes in microstructure by F. Osmond ; solubility in acids by E. Heyn and O. Bauer ; sp. gr. by E. Maurer ; hardness, K. Honda and K. Tamaru ; thermal expansion, T. Matsushita ; X-ray spectrum, K. Heindlhofer ; electrical resistance, B. D. Enlund ; thermoelectric force, S. Sato ; magnetization, S. Sato ; and coercive force, E. Maurer. S. Sato showed that there is a small evolution of heat at about 150°, and this represents the change of α-martensite into β-martensite ; a relatively large evolution of heat occurs in the range 260° to 300° due to the decomposition of β-martensite into troostite. Retained austenite decomposes into α- and β-martensites when it is cooled down to the temp. of liquid air, or more easily, when magnetically agitated in this cooled state. The retained austenite decomposes through α- and β-martensites into troostite when heated between 260° and 300°, and this is attended by a relatively large evolution of heat. K. Honda and T. Matsushita considered this thermal change to be due to the decomposition of β-martensite ; and E. Maurer and G. Schilling, G. Tammann and E. Scheil, and A. Merz and
FIGS. 109 and 110.—The Thermal Effect and the Dilation of Hardened Steel when Annealed at Different Temperatures.

C. Pfannenschmidt regarded it as a result of the decomposition of austenite. According to S. Sato, there is a contraction in the range from 300° to 400°, and this is attended by a distinct evolution of heat. It is supposed to be produced by the lattice building of cementite particles or molecules. α-iron which has been mechanically strained during quenching begins to recrystallize between 450° and 600° and this is attended by a relatively small evolution of heat. The subject was discussed by S. Sato, K. Tamaru, and K. Kawakami.

G. Tammann and E. Scheil compared the thermal effect, Fig. 109, with the annealing of a steel hardened by cooling to 0°, and the same steel again cooled in liquid air at —180°. The steel had 1·72 per cent. of carbon. There are three critical points on the curves : (i) at about 100° there is a change due to the transformation of martensite ; (ii) at about 250°, a change due to the transformation of austenite ; and (iii) at about 300° there is a change which is not due to the transformation of austenite, because it is accentuated with the steel cooled in liquid air. It is thought to be due to a second transformation of the martensite. These changes were discussed by K. Honda, S. Sekito, and A. Merz and C. Pfannenschmidt ; but T. Matsushita and K. Nagasawa supposed the transformation to be due not to a transformation of martensite, but to a change in the nature of the carbon associated with the iron. The properties of the structural constituents in these changes are summarized by E. Scheil in Table XII. K. Honda found that the specific properties X—hardness, electrical conductivity, and the intensity of

magnetization—of austenite, β-martensite, and a-martensite are related as $X_{aus.}$ $<X_{a\text{-mar.}}<X_{\beta\text{-mar.}}$, and the sp. vol., v, as $v_{aus.}<v_{\beta\text{-mar.}}<v_{a\text{ mar.}}$.

TABLE XII.—THE PROPERTIES OF THE CONSTITUENTS FORMED IN THE ANNEALING OF HARDENED STEEL.

Property	First martensite transformation (about 100°)	Austenite transformation (about 250°)	Second martensite transformation (about 300°)
Volume . . .	Decrease	Increase	Decrease
Hardness . .	Initial increase, then decrease ; at higher temp. only decrease	Increase	With low carbon, initial feeble increase, then in all cases strong decrease
Acid attack . .	As with hardness	Increase	Initial increase, then decrease
Electric conductivity	Increase	Increase	Increase
Heat transformation	Feebly exothermal	Strongly exothermal	Feebly exothermal
Lattice change .	Tetragonal to cubic space - centred. Interference sharp	Face-centred cubic to space-centred cubic	Parameter changes. Interference sharper
Magnetic—			
Saturation . .	Small increase probable	Strong increase	Small increase probable
Remanence . .	—	Increase	Probable increase
Coercive force .	Decrease	Increase	Initial increase, then decrease

The second transformation of martensite may be a continuation of the first transformation, or it may be the result of some intermediate stages in the transformation of martensite to pearlite. The modification in the equilibrium diagram for austenite and martensite founded on E. Maurer's hypothesis that martensite is a solid soln. of carbon in a-iron is shown in Fig. 111. The equilibrium curve of
FIG. 111.—E. Maurer's Austenite-Martensite Diagram.
FIG. 112.—G. Tammann and E. Scheil's Austenite-Martensite Diagram.

austenite and martensite is represented by an extension of the lines GP and GS beyond the pearlite line PSK. If the martensite is a solid soln., its physical properties will change continuously with the carbon content, and this conclusion is in agreement with the measurements of E. Gumlich, E. Maurer, and C. Benedicks on the electrical conductivity, and with those of N. Seljakoff and co-workers, and W. L Fink on the change of the lattice parameter. The facts also fit the hypothesis of G. Tammann and E. Scheil that instead of a-iron a similar but unstable form a'-iron occurs as a phase in martensite. This renders the

modification indicated in Fig. 112 necessary, where the dotted lines refer to the a'-martensite. In this case, it is supposed that at 100° carbon separates along $P'U'$ in accord with its solubility in a'-iron, and at 300° there is a transformation of the cementite-saturated a'-solid soln. into a-iron. If so, above the solubility limits of the carbon, the transformation into a'-iron must be independent of the carbon content.

There is also the hypothesis that the second martensite effect is the result of the formation of an intermediate unstable carbide which possesses the required properties. This hypothesis was explored by S. Hilpert and T. Dickmann, E. D. Campbell, and H. Hanemann and L. Träger. There is also the hypothesis that the second martensite transformation is a recrystallization of the martensite—*vide supra*; and the ϵ-η-hypothesis of H. Hanemann.

H. Hanemann observed that when austenite changes into martensite, e.g. by quenching in liquid air, the crystals of martensite contain less carbon than the adjacent austenite. According to H. Hanemann and A. Schrader, an examination of the martensite of steels with 0·05 to 0·2 per cent. of carbon tempered under various conditions shows that in addition to phases involving a- and γ-iron, there are also two phases involving ϵ-iron, θ-iron, and η-iron. The ϵ-**martensite** and η-**martensite** are in metastable equilibrium with austenite, and have the constitutional diagram, provisionally represented by Fig. 113; that is, they form a peritectoid equilibrium. The iron-cementite equilibrium diagram was called the metastable system I, and the martensite system, the metastable system II. The conc. of the carbon at U is near 0·10 per cent.; at V, 0·89 per cent.; and at W, 1·40 per cent. The critical temp., T, is near the A_3-point; and AVW, 325°. The critical temp. at 685° was observed with a 0·07 per cent. carbon steel; it is not a delayed $\gamma \rightarrow a$ change, because the difference is too large to be explained
FIG. 113.—Supposed Phases in the Martensite System.

as a super-cooling effect. They call T the Ar″ transformation. With rapid quenching of steels with 1·40 per cent. of carbon in liquid air, the formation of cementite and of troostite can be prevented, and the transformation of γ-**martensite** follows approximately the courses indicated by Fig. 113. TW, between 850° and 325°, represents the line along which ϵ-martensite separates from γ-martensite, and AW, the line along which ϵ-martensite reacts with γ-martensite to form either a mixture of ϵ- and η-martensites or of η- and γ-martensites, depending on whether the proportion of carbon is greater or less than 0·89 per cent. On quenching 0·89 per cent. carbon steel, ϵ-martensite of 0·10 per cent. carbon reacts at 350° with γ-martensite of 1·4 per cent. carbon to form η-martensite with 0·89 per cent. of carbon. If the carbon is between 1·40 and 1·70 per cent., the peritectoidal reaction just indicated does not occur, and η-martensite separates from γ-martensite—*vide infra*, tempering. The microsection, Fig. 114 ($\times 1200$), shows ϵ-martensite in long narrow needles surrounded by darkly etched η-martensite which stands in relief. The specimen contained 0·13 per cent. of carbon, and 0·5 per cent. of manganese; it was kept 45 mins. at 1120°, cooled slowly to 920°, and then rapidly quenched in liquid air. Fig. 115

(× 1200) shows dark needles of ε- and η-martensite in a light ground-mass of austenite ; the specimen contained 1·23 per cent. of carbon and 0·41 per cent. of manganese ; it was held 30 mins. at 1100°, cooled to 960°, and then quenched in liquid air. Fig. 116 (× 150) shows η-needles. The sample contained 1·75 per cent. carbon and 0·64 per cent. of manganese ; it was held 30 mins. at 1125°, tempered at 200°, cooled to −20°, and afterwards in liquid air. There are thus formed two sets of needles of η-martensite ; those formed by the liquid air quenching are etched lightly. The η-phase is J. O. Arnold's hardenite. The θ-phase, or θ-martensite, was demonstrated by K. Gebhard and co-workers, H. Birnbaum, and T. Matsushita. It was called heynite, after E. Heyn. It is found in hardened steel containing 0·3 to 0·4 per cent. of carbon. The subject was discussed by H. Hanemann and L. Träger, E. Maurer and G. Riedrich, and K. Gebhard and co-workers. J. Orland, and K. Gebhard and co-workers also agree that martensite consists of two phases involving a metastable system. In the metastable system ε-iron occurs in steels with up to about 0·1 per cent. of carbon ; in steels with from 0·1 to 0·37 per cent. of carbon martensite consists of ε-iron and heynite ; while in steels with 0·37 to 0·9 per cent. of carbon the constituents are heynite and hardenite ; and with steels with over 0·9 per cent. of carbon, hardenite and austenite. If equilibrium
FIGS. 114, 115, and 116.—Forms of Martensite (H. Hanemann and A. Schrader).

is not completely established, heynite may occur with steels with over 0·9 per cent. of carbon, and austenite in steels with less carbon.

F. Osmond applied the term troostite—after L. Troost—to a transitional form of the solid soln. of carbide in iron between martensite and pearlite. It comes between martensite and sorbite, or martensite and osmondite, so that it is regarded as martensite arrested while changing into sorbite or osmondite—vide infra, tempering. Troostite is obtained by modifying the speed of quenching. F. Osmond, and H. le Chatelier obtained it in the cold by quenching steel with different proportions of carbon during the recalescence period, i.e. when martensite is changing to pearlite ; by a mild quenching of small pieces in oil or boiling water from a temp. above the critical point ; or by a mild tempering (q.v.) of martensite between 100° and 260°. The X-radiograms agree with the assumption that troostite, like sorbite and pearlite, is a mechanical mixture of ferrite and cementite. H. C. Boynton said that it is produced when a metal with 0·45 per cent. carbon is cooled down to the A_1-arrest and then quenched in water at atm. temp. It is formed by heating martensite or austenite to 400°, or by cooling the steel to the temp. of liquid air. B. D. Enlund observed that with quenched or martensitic steels the conversion of martensite to troostite occurs ·between 100° and 200°. The subject was discussed by A. E. Cameron and I. F. Morrison, O. V. Greene, D. K. Bullens, A. Schrader, and K. Tamaru—vide infra, tempering. H. le Chatelier

obtained troostite by heating one end of a steel bar containing 0·9 per cent. of carbon, while the other end is free in air. There is thus a variation of temp. throughout the length of the bar. After quenching, the points of medium hardness are found by means of a file, and on suitably etching sections from these parts, untransformed pearlite will be found separated from completely transformed pearlite by a zone of troostite.

A. M. Portevin and M. Garvin observed that troostite formed in the neighbourhood of 600°, and martensite at 300°. L. Guillet found steels with 5 to 15 per cent. of chromium and over 0·5 per cent. of carbon have a structure of troostite mixed with martensite ; and steels with 3 to 12 per cent. of manganese and over 0·5 per cent. of carbon may consist of troostite above or admixed with martensite. H. le Chatelier, and H. von Jüptner observed that when troostite is formed by quenching from the recalescence period, there is a sudden contraction, indicating a molecular change in the metal. W. C. Roberts-Austen said that it is a modification of cementite ; and H. le Chatelier, a solid soln. of carbide in iron, differing from martensite and austenite in being magnetic at the temp. of its formation
FIG. 117.—Small Cells of Troostite in   FIG. 118.—Troostite in Martensite
Martensite.   (F. F. Lucas).

H. M. Howe regarded it as a mixture of austenite, ferrite, and cementite in varying proportions. T. Matsushita and K. Nagasawa considered troostite, formed by tempering austenitic steels for 20 mins. at 100° to 300° and again cooling, is made up of α-iron with the elemental carbon precipitated in a highly dispersed form, so that it is nearly optically homogeneous. C. Benedicks added that the electrical resistance and sp. vol. of troostite behave like pearlite, that is, like a mechanical mixture of ferrite and cementite. Z. Jeffries and R. S. Archer observed that the tempering of martensite is attended by (i) the growth of ferrite and the precipitation of carbide, and (ii) the growth of cementite particles.

F. Osmond said that the microstructure of troostite can be resolved and recognized by polishing and etching with liquorice root, or ammonium nitrate, when it assumes a yellowish-brown colour, or blue bands merging into one another. When slightly etched with dil. tincture of iodine it appears as brown bands in the shape of needles resembling martensite but surrounding grains of hardenite—saturated martensite—and with ferrite between the grains. It can also be etched by dil. alcoholic soln. of nitric acid, hydrochloric acid, or picric acid, or by W. J. Kurbatoff's reagent—a four per cent. soln. of nitric acid in isoamyl alcohol. H. von

Jüptner referred to troostite as a jagged constituent between martensite and cementite. According to H. C. Boynton, the hardness of troostite is 88 when that of martensite is 239 and that of ferrite is unity—*vide infra*, hardness. The structure of troostite is illustrated by Fig. 117 (× 500), of a steel with 0·869 per cent. of carbon heated for an hour at 700°, 15 mins. at 800°, and quenched in water at 18° ; it was then etched with a soln. of hydrogen chloride in amyl alcohol. The small dark cells of troostite are embedded in paler cells of martensite : Fig. 118 (× 150) shows the dark troostite in steel with 1·5 per cent. of carbon ; and Fig. 119 (× 2400), by

F. F. Lucas, shows nodular troostite in a steel containing 2·65 per cent. of carbon and 0·07 per cent. of manganese, and etched with picric acid. Highly magnified photographs of troostite were also made by R. A. Hadfield and T. G. Elliott. Troostite thus appears as dark-coloured, irregular areas which represent sections through nodules ; it is generally accompanied by martensite or sorbite, or both, or else it appears as a membrane surrounding martensite grains. F. F. Lucas described two types of troostite ; one he called nodular, and the other floccular ; and J. H. Whiteley also considered two types of troostite, which he called *troostite-M*, and *troostite-A*. According to F. F. Lucas, in hypoeutectoidal steels the troostite is accompanied by ferrite, and in hypereutectoidal steels cementite, and even

FIG. 119.—Troostite in Martensite (F. F. Lucas).

pearlite, may be present ; this, said A. Sauveur, indicates that the iron in troostite is capable of dissolving carbon as carbide up to the eutectoidal point, and hence he argued that the iron of troostite is in the β-state, because (i) α-iron can dissolve only about 0·05 per cent. of carbon and only carbide should be rejected by the cooling of troostite ; and (ii) the X-radiogram shows that it is not γ-iron.

H. C. Boynton adopted the hypothesis that troostite is a form of carbonless iron—ferrite—and since its properties, particularly its black colour on etching, differ so much from those of α-iron, he concluded that it was β-iron. F. Osmond originally thought that troostite is some transitory association of β-iron and carbon, but he abandoned the hypothesis. F. Rogers, W. J. Kurbatoff, and C. Benedicks regarded troostite as a soln. of elementary carbon, not carbide, in iron ; but C. Benedicks showed that this hypothesis is not probable ; rather is F. Osmond's opinion that troostite is an intermediate form between martensite and pearlite more likely. F. Osmond described troostite as being nearly amorphous, slightly granular, and mammillated. J. O. Arnold described what appears to have been F. Osmond's troostite as emulsified carbon present in an exceedingly fine state of subdivision in tempered steels ; and W. C. Roberts-Austen's definition of troostite was practically the same. C. Benedicks added that there is a continuous transition between troostite and pearlite, and that troostite is pearlite with ultramicroscopically small particles of cementite with the iron in the α- or β-state ; it is that part of martensite in which the cementite has just begun to form—incipient pearlite formation—but owing to the rapidity of cooling, the separate particles of cementite have not attained such a size that they can be distinguished microscopically. As observed by E. Heyn, in hypoeutectoid steels troostite occurs as a zone following the borders of the ferrite ; troostite has not been observed within the martensite where it is not in contact with ferrite ; while in hypereutectoid steel troostite occurs by preference in contact with cementite, and W. J. Kurbatoff, and C. Benedicks said that the centre of the patches of troostite generally contain

cementite. In agreement with C. Benedicks' assumption that troostite is a colloidal soln. of cementite, that is, a pearlite with ultramicroscopically small particles of cementite, W. J. Kurbatoff said that there is no clear boundary limit between pearlite and troostite, so that it appears as if troostite is a pearlite composed of very thin laminæ—*vide infra*, sorbite. A. McCance also concluded that (i) troostite consists essentially of α-iron which is in the amorphous state and not as it is in the crystalline form of ferrite, and (ii) that troostite contains carbon in suspension, and not in soln. as iron carbide. The magnetic permeability of quenched or tempered steel is greater as the amount of contained troostite increases, and consequently the iron is present in the α- and not in the β-state. The growth of troostite was studied by S. Sato.

According to F. F. Lucas, in nodular troostite there is a crystalline growth about a nucleus, probably a result of the reorientation of freshly formed particles of α-iron about an inclusion or pore, or along a grain boundary of crystallographic plane. The carbide collects in very thin plates, forming a laminated or sandwich structure with the ferrite. Pearlite is formed under one set of conditions. The microscopic pattern which results is a visible manifestation of the way the transformation occurs. If rapid, the pattern is acicular; if less rapid, nodular. K. Honda believes that martensite forms first and troostite next. There is nothing to show that the needles are formed first and nodules second. If this were the case, nodules would sometimes appear with partially absorbed or transformed needles sticking out of their outlines, but none such has been seen. According to F. F. Lucas, the difference between martensite needles and troostite nodules does not lie in the ultimate constituents, for both seem to be composed of α-iron and iron carbide. The difference is the way in which the two structural forms have developed, and the grain-size of the particles of the carbide. There is a midrib in the martensitic needles indicating the plane along which decomposition first occurred. On each side of the midrib there is a tapering zone. These zones are not as fully transformed as the midrib, because the midrib etches out, forming a trough. The inner crystalline orientation of the needles appears in all cases to be the same as the orientation of the original austenite. In troostite, however, there is very definite evidence that the larger nodules develop about a nucleus, usually a pore or an inclusion, and they form into spheres. The nuclei at the centre of the nodules have grains radiating from them. A section of a troostitic nodule often looks like a wagon wheel in which the hub is the nucleus and the spokes are grain boundaries. In the case of troostite the freshly transformed α-iron appears to have been reoriented without following in all details the old austenite crystalline symmetry. The subject was discussed by N. T. Belaiew.

In the passage from martensite to pearlite, the colloidal theory of C. Benedicks assumed that martensite first changed into a colloidal soln. of cementite in ferrite, and that by the coalescence of the individual particles of ferrite and of cementite pearlite was produced. The nascent, unresolved pearlite was called troostite. Troostite thus differs from pearlite solely in its mechanical state of aggregation. According to the osmondite theory of E. Heyn and O. Bauer, it is assumed that a definite substance which they called **osmondite**—after F. Osmond—is formed as an intermediate stage in the passage of martensite to pearlite. The characteristics of osmondite are: (i) It is not cementite. (ii) It is more readily attacked by dil. sulphuric acid than martensite, ferrite, or cementite—*vide infra*, Fig. 131. The solubility curve shows a maximum with the formation of osmondite, and it diminishes in both directions towards martensite and towards pearlite. The transition stages between martensite and osmondite may therefore be denoted by the generic term troostite, and those between osmondite and pearlite, by sorbite. When dissolved in 10 per cent. sulphuric acid, out of contact with air, the troostites leave no carbon residue but a residue rich in carbon containing little or no iron. The whole carbon content of the residue does not dissolve in hot conc. hydrochloric acid, but all the iron is extracted by that solvent. The free carbon so obtained is

distinct from the carbide carbon, which remains combined as carbide on dissolving steel in 10 per cent. sulphuric acid out of contact with air. This carbide is dissolved by hot conc. hydrochloric acid, giving off hydrocarbon gas, and leaves no carbon residue. This carbide first occurs in sorbites, and increases in quantity as the temp. of tempering increases up to the pearlite stage, the carbon of which is nearly all present as carbide. (iii) The colouring of all tempered steels in the presence of alcoholic hydrochloric acid, as well as the colouring of troostite and osmondite in hardened steels, is caused by the separation of free carbon. Osmondite contains the maximum amount of carbon, and is coloured darkest. (iv) When hardened or martensite steel is tempered, most of the heat is liberated below 400°. The transition from martensite to osmondite is therefore accompanied by the liberation of most of the heat, whereas the amount of heat liberated in the passage from osmondite to pearlite is very limited. (v) The segregation of one or more solids, x, from the solid soln. of martensite during its tempering up to about 400° may proceed ultramicroscopically or microscopically. The x gives up the maximum amount of free carbon when treated with dil. sulphuric acid, and the amount of x therefore increases in passing in the troostites from martensite to osmondite, and decreases in passing in the sorbites from osmondite to pearlite. Osmondite was discussed by J. Calian, E. Maurer, and O. V. Greene.

J. O. Arnold noted that the passage of hardenite into normal carbide is accompanied by the evolution of heat ; it commences at about 100°, the change is more rapid at 250°, reaches a maximum velocity at about 300°, and is complete at 400°. E. Heyn and O. Bauer observed the maximum evolution of heat at 360°. According to H. le Chatelier's hypothesis, the x is a carbide, and, according to C. Benedicks, a colloidal soln., which may be called *cementite-ferrosol*. H. le Chatelier's carbide shows reactions different from those of the normal carbide, and it is changed at 400° into stable carbide ; and C. Benedicks' colloidal soln. is a metastable intermediate form which also passes into stable pearlite. W. Fränkel and E. Heymann inferred that an iron carbide of high carbon content, say $FeC_{8\ to\ 10}$, will be established ; at present it is believed that osmondite and troostite contain the same carbide, Fe_3C. Osmondite is regarded as a state of steel exhibiting a maximum content of troostite, and thereby presenting a maximum speed of etching or dissolution in acids. Osmondite, said E. Heyn and O. Bauer, is characterized by : (1) a maximum degree of solubility ; (2) a maximum yield of free carbon when treated with dil. sulphuric acid ; (3) a maximum degree of dark colouring when etched with alcoholic hydrochloric acid ; (4) a change in the direction of the curve for remanence and coercive force ; and (5) a maximum sp. gr. The troostites contain carbon which remains as free carbon when treated with dil. acids, and also carbon which escapes during dissolution in 10 per cent. sulphuric acid ; the sorbites contain in addition carbide carbon. The subject was discussed by H. M. Howe ; and C. Benedicks, T. Matsushita and K. Nagasawa regard osmondite as a form of sorbite.

F. Osmond applied the term **sorbite**—after H. C. Sorby—to pearlite which has not segregated into the well-defined lamellar form. F. Osmond said that when the tempering is sufficient to efface the structure of martensite, it forms troostite ; and sorbite is pearlite that has not succeeded in being segregated for want of time or some other reason. Hence sorbite is unsegregated pearlite, a kind of transitional form between martensite, osmondite or troostite and pearlite—*vide infra*, tempering. Sorbite is produced by tempering quenched martensite steels at 300° to 400° for 20 mins. and cooling. Sorbite has been regarded as ultramicroscopically fine-grained pearlite. W. D. Bancroft, J. Alexander, H. le Chatelier, V. Kohlschütter and K. Steck, and F. C. A. H. Lantsberry discussed the colloidal structure of steel. T. Matsushita and K. Nagasawa regard sorbite as a mixture of iron with highly dispersed cementite. Heating troostite to 300° or 400° makes the dispersed carbon of troostite form cementite. The mixture of troostite and sorbite formed by tempering at 300° to 400° has been called osmondite—*vide supra*. If sorbite

be heated to 450° or 500°, it forms granular pearlite. Some consider *granular pearlite* or *granular cementite* to be sorbite. Hence it is also called *sorbitic pearlite*, and when referring to the contained carbon, *sorbitic carbide*. F. Körber and W. Köster studied the granular cementite; and O. V. Greene, the structure of sorbite. Troostite of eutectoidal composition transforms into sorbite by forming α-iron; hypoeutectoidal steel forms sorbite after rejecting excess ferrite; and hypereutectoidal steel forms sorbite after rejecting excess cementite. In 1895 J. O. Arnold said that normal iron carbide exists in three distinct modifications, each one conferring upon the iron in which it is found particular mechanical properties : (i) emulsified carbide, present in an exceedingly fine state of subdivision in tempered steel ; (ii) diffused iron carbide, occurring in normal steels in the form of small, ill-defined striæ and granules ; and (iii) crystallized iron carbide, occurring as well-defined laminæ in annealed and in some normal steels. The first of these forms is presumably the so-called troostitic carbide, and the second, the so-called sorbitic carbide.

Consequently, sorbite cannot be properly called a constituent of hardened steel, but it can be regarded as a connecting link between annealed or pearlitic steels and hardened or troostitic or martensitic steels. The X-radiogram indicates
FIG. 120.—Granular   FIG. 121.—Lamellar   FIG. 122.—Sorbite
Pearlite or Sorbite   Sorbite (F. Osmond).   (F. T. Sisco).
(E. Heyn).

that sorbite, like troostite and pearlite, is a mechanical mixture of ferrite and cementite. N. Yamada found that at a given temp. the sp. hts. of troostite and sorbite are the same as that of pearlite. This agrees with the view that all three differ only in the degree of coagulation of the cementite particles and the mode of distribution. Sorbite is stronger, harder, and less ductile than pearlite, but softer and more ductile than troostite. H. C. Boynton represented the hardness of sorbite by 52 when that of troostite is 88, that of pearlite 4·3, and that of ferrite unity— *vide infra*, hardness. J. E. Stead and A. W. Richards discussed sorbitic steel for rails. H. C. Boynton found that the production of sorbite is favoured by: (i) a high temp. at which cooling commences ; (ii) a small sample ; (iii) keeping the sample a long time at a high temp.; and (iv) rapid cooling. According to C. Benedicks, if martensite or austenite has begun transformation which ultimately results in pearlite, troostite is formed ; and if the martensite has not been completely resolved into pearlite, sorbite appears. Troostite is the first and sorbite is the last stage in the transformation of martensite to pearlite. Thus sorbite can be regarded as an uncoagulated mixture of the constituents of troostite and of pearlite. J. O. Arnold doubted the wisdom of applying definite terms to indefinite transition products like sorbite and troostite. The time-honoured Fig. 121 ($\times$1500), representing lamellar sorbite, is due to F. Osmond ; and Fig. 120 ($\times$1240),

representing granular pearlite, or sorbite, from a forged bar of crucible steel with 0·92 per cent. of carbon, is due to E. Heyn. Fig. 122 (×500), by F. T. Sisco, represents the sorbite in a steel with 0·30 per cent. of carbon and etched with alcoholic nitric acid. Some highly magnified microphotographs were prepared by R. A. Hadfield and T. G. Elliott. Sorbite contains : (i) hardening carbon or cementite in soln., which makes it harder and stronger than pearlite ; (ii) α-iron, which makes it magnetic and relatively soft ; and (iii) crystalline cementite. Sorbite is formed on tempering austenitic, martensitic, or troostitic steels. F. Osmond obtained sorbite by cooling steel slowly enough to allow the transformation to produce an imperfect separation of ferrite and cementite. This is done by the cooling in air of small samples, and then quenching in cold water or molten lead towards the end of the recalescence. Sorbite gives a brown colour when it is etched by polishing, or by iodine, or dil. acids. H. von Jüptner suggested that sorbite contains $(Fe_3C)_3$ in soln., but there is no trustworthy evidence in support of this. The subject was discussed by A. Schrader.

H. C. Sorby applied the term *pearly constituent of steel* to the material in steel which, when lightly etched, showed a peculiar play of colours suggestive of mother-
FIGS. 123, 124, and 125.—Structure of Pearlite.

of-pearl. The plates are rarely over 0·001 mm. in thickness, and the plates of carbide-cementite, being much harder than the ferrite plates, stand in relief after polishing. This results in an arrangement resembling a refraction grating which produces the appearance of mother-of-pearl, particularly with oblique illumination. H. M. Howe called it **pearlite.** H. C. Boynton found that its hardness is 4·3 when that of ferrite is unity and of cementite 272 ; but that, according to A. M. Portevin, the hardness of eutectics varies with the fineness, the shape, and the distribution of the eutectic particles. A. M. Portevin, and C. Benedicks studied the effect of an excess of one component of the eutectic in modifying its structure. F. L. Brady discussed the effect of the surface tension of the constituents on the eutectic structure. H. von Jüptner gave 7·74 for the sp. gr. of pearlite. Pearlite consists of alternating layers of cementite and ferrite or sorbite, or grains of cementite embedded in ferrite or sorbite. Fig. 123 (×500) shows the pearlite in rolled steel with 0·869 per cent. of carbon ; and Fig. 124 (×500), the pearlite in the same steel after heating to 1040° for 6 hrs. and then slowly cooling. Fig. 125 (×500) shows the pearlite in a steel with 1·3 per cent. of carbon, which had been heated for 12 days to 1100° in wood-charcoal. Some cells of cementite occur in the broad

cells of pearlite. All three specimens were etched with a soln. of hydrogen chloride in amyl alcohol. Some highly magnified microphotographs were prepared by R. A. Hadfield and T. G. Elliott. Fig. 126 ($\times 300$) shows a photograph after F. T. Sisco in a steel with 0·90 per cent. of carbon and etched with alcoholic nitric acid. The plates of carbide-cementite remain bright, for they are not affected by the ordinary etching agents, while the ferrite plates appear dark, because (i) they are tarnished by the etching, and (ii) they are depressed owing to their greater softness, and they stand in the shadow of the plates of the cementite-carbide. M. Mikami raised the question whether the white or the dark parts in pearlite are cementite or ferrite, but was unable to satisfy himself with an answer, because in lamellar pearlite the top of the lamellar cementite in relief appears white, whilst the side faces are dark; and because the bottom of the

Fig. 126.—Minute Structure of Pearlite (after F. T. Sisco).

lamellar ferrite between two consecutive lamellar cementites also appears white, whilst both edges are dark.

The pearlite may take on forms other than the lamellar arrangement; thus, it may appear granular—vide supra, sorbite. M. Oknof showed that pearlite forms a continuous connected network which is permeated throughout with cementite or ferrite grains. The percentage of carbon in pearlite is somewhere between 0·8 and 0·9 per cent., and this represents the composition of the eutectoid mixture, at the eutectic temp., corresponding with the A_1-arrest, Fig. 128. At this temp. the solid soln., austenite, martensite, or hardenite, is transformed into the pearlite aggregates of ferrite and cementite. This transformation implies the passage of γ-iron to β- and α-iron, or to α-iron directly; the crystallization of α-iron into parallel plates, or lamellæ; and the formation and crystallization or crystallization only of the cementite, Fe_3C, into parallel plates alternating with the plates of ferrite. W. E. Dalby said that steel containing about 0·9 per cent. of carbon is built up of blocks of pearlite, and that pearlite consists of alternating sheets of iron and cementite, packed closely together, 60,000 to the inch, and that these packed sheets are bent into shapes suggesting that their final forms have been developed by the complicated play of internal molecular forces. The structure of pearlite was discussed by H. E. Publow and co-workers, and H. Styri; and the effect of grain-size on the rate of formation of pearlite, by U. Dehlinger.

G. Tammann and E. Scheil said that the transformation of austenite into pearlite may take place at 100°. Pearlite so produced has a greater sp. vol. than the pearlite of soft steel, but the excess decreases with rise of temp., and vanishes at about 500°. The transformation of austenite and martensite to pearlite may be continuous or discontinuous, passing through intermediate stages represented by:

$$\text{Austenite} \rightleftharpoons \text{Martensite} \rightleftharpoons \text{Troostite} \rightleftharpoons \text{Sorbite} \rightleftharpoons \text{Pearlite} \begin{cases} \text{Ferrite} \\ \text{Cementite} \end{cases}$$
By suitably varying the rate of cooling, the alloy may be retained at ordinary temp. in any of these intermediate states. This depends on the fact that the change

from austenite to pearlite is a time reaction, and if the time occupied in cooling through the critical range is less than that required for the complete transformation, one or other of the intermediate states persists. It is also assumed that the intermediate states are stages in a continuous change ; that the reaction which has been arrested by abrupt cooling will be resumed when the steel is reheated ; and that the results obtained by cooling at different rates or rapid cooling followed by reheating to different temp. are different means of attaining the same object—namely, arresting the austenite⇌pearlite transformation at an appropriate stage. As J. M. Robertson has shown, these assumptions are not quite right. The effect of speeding up the rate of cooling not only restricts the time taken to cool through the critical range, but it also lowers the temp. at which the transformation begins— *vide infra*, the doubling of the Ar_1-arrest.

K. Honda showed that since the Ar_1-arrest represents the change of soln. of carbon in γ-iron into a mixture of α-iron and cementite, the transformation of austenite into pearlite involves a sequence of consecutive reactions : (i) a change in the configuration of iron atoms from the face-centred to the body-centred lattice ; and (ii) the separation of carbon atoms from the interspaces of the lattice, (iii) to form cementite as they leave the lattice ; otherwise expressed, the Ar_1-transformation involves the changes : austenite→martensite→pearlite. With extremely rapid cooling a martensite mixed with some unchanged austenite is formed, and in some cases the troostite develops in a granular form about the boundary of the austenite. This does not mean that troostite is formed directly from austenite. X-radiograms show that troostite, sorbite, and pearlite are all mixtures of α-iron and cementite, hence the change from austenite to troostite necessarily involves a change in the configuration of the iron-lattice to form martensite, and the subsequent change of martensite into α-iron and cementite. K. Honda and A. Osawa also found that in quenched steels the amount of retained austenite is greater on the outer layer than in the inner one. For the same steel this difference increases as the quenching temp. is raised, and for the same quenching temp. it increases as the carbon content. M. Chikashige interpreted the A_1-transformation by the following scheme :

Pearlite—stable

Austenite ————→ Martensite—unstable but realizable
below 721°
The subject was discussed by T. Murakami. The formation of cementite from austenite was discussed by H. Hanemann and O. Schroder, and R. H. Mehl and co-workers. The thermal value of the change austenite→pearlite at 700°, the Ar_1-arrest, was found by K. Honda to be 18·2 cals., in agreement with values by P. Weiss and N. Beck, and A. Meuthen. K. Honda gave for the transformation austenite→martensite 4·3 cals. ; so that the change martensite→pearlite approximates 13·9 cals., provided that the sp. hts. of pearlite and martensite are the same at 700°. The subject was also discussed by K. Honda and T. Kikuta, M. Chikashige, and E. Scheil. Immediately after the Ar_1-arrest and the α-iron and the tritacarbide or cementite have separated, the two constituents are in a very fine state of subdivision, so that if the mixture be kept in that state by abruptly cooling the mass, the intermediate stages appear, but if the mass be kept at a temp. just below the Ar_1-arrest, the fine particles of each constituent coalesce to form alternate layers or bands of ferrite and cementite. If, however, the time be prolonged, the plates become thicker, until finally the cementite becomes isolated in large patches surrounded by crystals of ferrite.

F. Osmond referred to the coalescence of the cementite in steels with less than 0·5 per cent. of carbon, where the pearlite areas become bounded by a belt of partly formed cementite with ragged edges which he termed *atolls*; the phenomenon was not observed in eutectic and hypereutectic steels. The balling-up—spheroidization, or *coalescence*—of the cementite lamellæ into globules or spheroids is dependent on the extent of the annealing, and it is found in well-annealed steels, malleable cast irons, and in grey cast irons. The different appearances furnished by the balling-up of the constituents of the pearlite have been called different names— *e.g. globular pearlite*; C. Benedicks thus recorded a bead-like variety—*beaded pearlite* or *necklace pearlite*. The strands of spherules represent a transition stage in the conversion of lamellar cementite into globules or spheroids. The **spheroidizing of the cementite,** particularly in high-carbon steels, is effected by heating the metal at or near the critical temp., followed by cooling slowly in the upper part of the cooling range. Fig. 127 ($\times 1000$), by R. S. MacPherran and J. F. Harper,

represents a steel with 0·45 per cent. of carbon and 0·57 per cent. of manganese, which has been treated three times, each time for about 48 hrs., at about 670°, so as to spheroidize the pearlite. K. Honda and S. Saito found that if a quenched specimen be heated to below the Ac_1-arrest, sorbitic cementite spheroidizes; if a hypereutectoid steel be heated above the Ac_1-arrest, but below the solubility line, and quenched, the supereutectoid cementite spheroidizes; if a lamellar, pearlitic steel be heated just up to or a little above
FIG. 127.—Spheroidized Pearlite.

the Ac_1-arrest for a certain interval, spheroidization occurs; and if granular pearlite be heated below the Ac_1-arrest for a sufficient length of time, spheroidization occurs. If the Ac_1-point be not attained, the spheroidization of the lamellar cementite does not occur. If the maximum temp. exceeds a certain limit above the Ac_1-arrest, and the steel be cooled, the cementite forms lamellar pearlite. The temp. interval of spheroidization in low-carbon steels is very small, extending only to about 20°; it increases rapidly with the content of carbon, and in high-carbon steels amounts to about 100°. A. Pomp and R. Wijkander found that spheroidal cementite dissolves more quickly than lamellar cementite, and consequently the latter form requires a more prolonged heating before the metal is quenched for hardening. The subject was studied by A. M. Portevin, D. Hanson, J. E. Stead, J. H. Andrew and H. A. Dickie, A. Schrader, H. C. Ihsen, A. M. Portevin and V. Bernard, H. Hanemann and F. Morawe, H. Hanemann and V. Lindt, H. M. Howe and A. G. Levy, A. Sauveur, A. L. Babochine, R. A. Thakore, A. E. White, C. H. Desch and A. T. Roberts, B. Stoughton and R. D. Billinger, M. Oknof, B. Kjerrman, A. Allison, N. G. Ilyne, J. H. Whiteley, J. O. Arnold, O. V. Greene, E. F. Lange, F. Osmond, P. Goerens, B. Ischewsky, N. T. Belaiew, and S. Kobayashi. T. Isihara studied the influence of various elements on the spheroidization of the carbides in steel. He observed that if manganese is present, the spheroidization interval of temp. above the

Ac_1-arrest is slightly increased proportionally with the manganese; and the increase of the interval of temp. is much greater with the addition of chromium or copper.

By varying the conditions of time and temp., almost any degree of fineness can be obtained between balled-up cementite and ultra-microscopic grains. Usually the pearlite in hypoeutectoidal steels is finely laminated, while that in hypereutectoidal steels is coarser. According to J. H. Whiteley, the temp. of the formation of pearlite in steels at the Ar_1-arrest is not constant, but is lowered by increasing the rate of cooling. Again, the presence of nuclei of cementite within the γ-iron region induces the crystallization of cementite and ferrite as globular pearlite at a temp. much higher than that at which growth occurs in the absence of nuclei. When the growth of lamellar pearlite has started, it proceeds gradually, so that it is possible by quenching to obtain a specimen with intermixed areas of pearlite and martensite. This all shows that there is a lag in the transformation at the Ar_1-arrest. By analogy with supersaturated soln. it is inferred that lamellar pearlite is formed from supersaturated solid soln. The delayed crystallization, said A. F. Hallimond, may be hastened by violent mechanical working, which in solid soln. is equivalent to the agitation or stirring of a liquid to initial crystallization. J. H. Whiteley also proved that when steel is in a metastable state at the temp. of the Ar_1-arrest, the lag, or delay in crystallization, is abbreviated. G. Tammann and G. Siebel found that the rate of formation of pearlite remains constant in steels with 0·23 to 0·96 per cent. of carbon until the rate of cooling has fallen to a critical value, after which it falls off rapidly. The maximum linear speed of transformation of γ-iron to pearlite was 550 mm. per sec. The speed of transformation increases with increasing proportions of manganese; and it is less in air than in hydrogen.

N. T. Belaiew studied the stereometry of pearlite grains. He found that the cementite lamellæ in a grain of pearlite are arranged roughly parallel to one another and to the crystallographic plane of the grain—presumably to one face of the cube. A secant plane perpendicular to that face will be normal to the lamellæ, and the angle of inclination, ω, for that plane will be zero. All the N lamellæ of the grain will appear on the normal plane; and the distance, $\triangle$, between two lamellæ on such a plane will be the actual distance, $\triangle_0$. As the angle ω increases, the number of lamellæ, n, seen on a section of the same grain decreases, and the apparent distance, $\triangle_\omega$, between two lamellæ increases. Since $\cos \omega = n/N = \triangle_0/\triangle_\omega$, the graph of natural cosines will show the ratio of the decrease in the number of lamellæ, and of the increase in the distance between the lamellæ—i.e. the coarseness of the structure of the lamellæ. Since $\triangle_0$ and $\triangle_\omega$ can be measured on a suitable microphotograph, the angle of inclination, ω, can be calculated from $\cos \omega = \triangle_0/\triangle_{\omega'}$. When the angle of inclination, ω, approaches 80°, distance $\triangle_\omega$ between the lamellæ becomes five times greater than $\triangle_0$; ten times greater when $\omega = 84°$; and twenty times greater when $\omega = 87°$. Hence the change in the aspect of the pearlite in different sections. Imagine an idealized pearlite with a hundred cementite films of thickness $100\mu\mu$ packed in alternate layers with ferrite lamellæ $300\mu\mu$ thick. The thin, rigid films of cementite thus appear embedded in a matrix of ferrite.

As steel cools it contracts, in accord with the laws of cooling bodies, but in passing through the Ar_1-arrest there is a sudden dilation resulting from the change from γ-iron to α-iron. The expansion in passing from a face-centred to a body-centred lattice is about 9 per cent., and the linear expansion about 3 per cent. This arrest in the contraction is followed by the normal cooling contraction. As a result, pearlite, during and after its formation, is subjected to stresses, so that the cementite lamellæ get warped and twisted, giving rise to steps in the cleavages; at the same time the ferrite lamellæ are split into a multitude of cubes. These deformations are in accord with C. G. Darwin's observations on the working and cracking of crystals. The dimensions of the ferrite cubes are of the order of magnitude of the wave-length of light. During the deformation of the cementite the ductile matrix of ferrite acts as a protective coating, and the brittle cementite

films can be more or less bent and distorted to produce a curvature of the cementite lamellæ in the pearlite. True cementite particles are usually acicular and straight, and when the cementite lamellæ in pearlite are straight, they are close to free cementite, suggesting an earlier stage of crystallization. The structure of eutectics was discussed by C. Benedicks, A. M. Portevin, C. H. Green, and F. L. Brady ; and the theory of labile and metastable soln.—1. 9, 6—by A. F. Hallimond.

The Hindoo steel, **damascene** or **damascus steel,** called in Russia *poulad* or *bulat*, appeared in Western Europe during the Middle Ages. It often came via Damascus—hence the name. The same steel appeared on the European markets in the seventeenth century, as **wootz** or *wooz*. Various early writers have referred to the manufacture of this steel—J. Chardin, P. Anossoff, R. A. Hadfield, J. B. Tavernier, H. W. Voysey, P. Oberhoffer and co-workers, J. M. Heath, D. Mushet, D. Lardner, M. Bazin, G. Pearson, F. Buchanan, etc. Allusions to the famous sword blades of India are frequent in Arabic literature ; the *ondanique* of Marco Polo is considered to have been a fine steel resembling Indian steel—*vide supra*, hardening steel. The history was discussed by N. T. Belaiew. H. Wedding gave an analysis of wootz steel ; A. R. Roy described its manufacture in India ; B. Neumann, and W. Guertler discussed the structure and manufacture. One external characteristic of the steel is its patterned surface markings, or surface-watering. Hence the Persian term *poulad jauher der*, meaning steel with a watered surface. Fig. 128 will give an idea of the surface of damascene steel. It is a photo-

FIG. 128.—The Surface of Damascene Blade—Khozassan watering.

graph by Col. Belaiew, from a damascene blade in the Wallace Collection which appeared in his *Crystallization of Metals* (London, 1922). The quality of the Oriental sword blades made from the steel appears to have been judged by the pattern of the watered surface. The pattern changes according to the proportion of carbon present in the steel, and P. Anossoff said that it ranges from parallel stripes to wavy ones, then to mottled ones. As the proportion of carbon increases the chequered mottle grows bigger, forms grape-vine patterns, and finally extends over the whole breadth of the metal, dividing it into almost even and equally patterned vertebræ. This is the most prized variety, and forms the Persian *kirk narduban*—the forty steps of Mahomet's ladder. The steel is extremely ductile, so that P. Anossoff could say that a blade of good damascene steel cannot be broken by bending, but can yet be bent to such an extent as to lose its elasticity. When bent in the usual fashion the blade flies back and retains its original shape ; and when bent more forcibly, say at a right angle, it does not break or lose its original elasticity when straightened out again. D. K. Tschernoff considered this kind of steel to be " the best ever manufactured." Analyses reported by R. A. Hadfield, I. Ilimoff, and N. T. Belaiew show that the proportion of carbon usually ranges from 1·0 to 1·80 per cent. The variegated surface of the Oriental swords was at first attributed to the metal having been compounded of bars and wires of iron and steel welded and wrought together, and then twisted by forging in various directions. J. Stodart and M. Faraday experimented on alloys of iron with various metals with the idea

of discovering the origin of the watering. J. R. Bréant assumed that the damask effect is due to the irregular distribution of carbon in the metal, whereby two distinct combinations are produced ; the slower the cooling, the larger the damask veins. The mode of manufacturing damascene steel was established by the experiments of P. Anossoff, and N. T. Belaiew. The conditions of annealing the hypereutectoidal steel are similar to those employed by H. M. Howe and A. G. Levy, and J. E. Stead for spheroidizing the cementite, and divorcing the eutectoidal pearlite so as to form globulites of cementite. Hence, said N. T. Belaiew :

> Bearing in mind that hypereutectoid steels spheroidize more readily than eutectoid, and that forging through the critical range facilitates the process very much, we must readily admit that structures such as those of the Oriental blades are usually arrived at without any additional tempering, but only through a very elaborate forging at comparatively low temperature. . . . The heating should be but slightly in excess of the critical temperature, bringing the article only partially to the austenitic stage, so that the cementite pattern remains practically intact. The hardening process then altered only the composition of the background, transforming it into a martensite stage, which finally, after annealing, was brought back to troostite.

In 1897, H. le Chatelier,[2] and in 1911, L. Grenet showed that the temp. at which martensite changes to pearlite, the A_1-arrest, is lowered by quenching. A. M. Portevin, A. M. Portevin and M. Garvin, H. Hanemann and co-workers, P. Chévenard, P. Dejean, K. Honda, K. Honda and T. Kikuta, and A. F. Hallimond found that with quenching, or very rapid rates of cooling, carbon steels give transformation points in the vicinity of 300°. M. Masloff emphasized the importance of the effect of the rate of cooling on the Ar_1-arrest, and K. Daeves illustrated the phenomenon by Fig. 129. The Ar_1-arrest is depressed to Ar' by
FIG. 129.—The Effect of the Rate of Cooling on the Ar_1-Arrest.

increasing the speed of cooling to Oa ; and any further increase in the rate of cooling depresses the Ar_1-arrest still more, but simultaneously a second arrest appears, Ar'', and troostite is formed. When the speed of cooling has increased to Ob, the Ar'-arrest disappears, and the Ar''-arrest alone occurs, with the formation of martensite—vide supra. This nomenclature is due to A. M. Portevin, who called the arrest between 700° and 600° the Ar'-arrest, and that between 500° and 250° the Ar''-arrest. This splitting, lowering, or **doubling of the Ar_1-arrest** was also observed by F. Osmond, during his study of the tungsten steels, in 1892 ; it is not to be confounded with the twinning of the A_2-arrest—vide supra. The phenomenon is fairly common with the alloy steels— vide nickel steels. Thus H. J. French and O. Z. Klopsch observed it during the cooling of a 0·98 per cent. carbon steel at various rates from 875°. It was also observed by T. Kikuta, H. C. H. Carpenter, K. Honda, T. Murakami, etc. K. Honda and T. Murakami, and A. Hultgren noted that the doubling of the Ar_1-arrest occurs with tungsten steels, and A. Hultgren, with chromium steels and nickel-chromium steels. With tungsten steel, containing up to 1·29 per cent. of carbon, the recalescence at Ar'' was identified with a separation of ferrite, usually as needles, called secondary ferrite, sometimes, but not always, depending upon subsequent rate of cooling. This is followed by carbide formation, visible as dark etching areas around the ferrite. Furthermore, by keeping the specimen during cooling at different temp. for varying lengths of time, followed by quenching, it was found that the quantity of ferrite formed increased with temp. and that it was a function of the temp. rather than of time. In other words, there appeared to be a metastable equilibrium between the ferrite and the austenite, probably corresponding with the stable equilibrium curves extended to lower temp. This explains why such unexpectedly great quantities of ferrite might be separated even in high-carbon alloy steels. That carbide is not set free

at the same time was tentatively explained by assuming that in an alloy steel, stabilized by heating to high temp., the rate of separation of carbide out of soln. was slower than that of ferrite. The ferrite formed etched like ordinary ferrite, but might on prolonged etching assume a light brownish tint, the more so the lower the temp. of formation.

It is generally assumed that sorbite and troostite are formed from pearlite at the Ar'-arrest, and martensite at the Ar''-arrest ; and there are now two hypotheses : (i) The Ar''-change is the completion of the consecutive series of changes : austenite⇌martensite⇌troostite⇌sorbite⇌pearlite interrupted at the martensite stage. If so, then the discontinuity in the lowering of the change from Ar' to Ar'' remains unexplained, for if one change is alone involved, it would probably be depressed progressively by an increase in the rate of cooling. (ii) The Ar'-arrest is a direct change from austenite to pearlite, sorbite, or troostite, and the Ar''-arrest a direct change to martensite. In general, a transformation in a pure substance is gradually lowered as the rate of cooling increases. This phenomenon is an effect of hysteresis or lag, but with an alloy of two or more metals, as in the case of the Ar_1-transformation of steel, a stepped change occurs. T. Murakami explained the doubling of the arrest as an effect of a kind of supercooling of the austenite in the changes : austenite $\rightarrow$ martensite $\rightarrow$ (ferrite+cementite) — *vide infra.* T. Murakami said that in chromium steels the doubling of the arrest is due to the presence of a chromium carbide, which, on passing into soln. at the Ac-arrest, dissociates into a simpler carbide and chromium, so that the chromium causes a doubling of the arrest on cooling. C. A. Edwards and co-workers concluded that the phenomenon was also dependent on the action of a chromium carbide, but gave the carbide a composition different from that found by T. Murakami. Both observers based their conclusion on the fact that the arrest is doubled only when the ratio of chromium to carbon exceeds a certain limit. W. T. Griffiths added that this does not agree with his observations that the percentage necessary to cause a complete depression of the Ar'-arrest depends not only on the proportion of carbon present, but also on that of nickel. A complete dispersion is also possible before the chromium : carbon ratio has attained the value necessary to give the carbide whose presence is considered necessary for the doubling of the arrest.

J. H. Andrew and co-workers said that a carbide expansion occurs above and during the Ac-arrest owing to the dissociation of a complex $(Fe_3C)_n$ into simpler molecules. This dissociation by increasing the mol. conc. in soln. causes a depression of the arrest. Chromium carbide also dissociated at high temp., the carbon remaining with the iron, and the chromium dissolving in the iron. Nickel and chromium act together in keeping the carbide in the dissociated state and thus assist one another in depressing the arrest. W. T. Griffiths added that increasing the carbon should give an increased tendency to the doubling of the point, since, with a given treatment, the conc. of the dissociated carbide molecules would then be likely to increase on soln. ; but this is not the case. If the hypothesis be correct, W. T. Griffiths also said that the temp. necessary to produce the conc. of dissociated molecules necessary to depress the point would be lower the higher the percentage of carbon. This is not in agreement with observation. Again, with either of the above hypotheses, it is necessary to assume that the carbides exist in solid soln. as such. Z. Jeffries and R. S. Archer hold that in austenite the carbide is dissolved as carbon atoms, not as carbide molecules, and this view is in agreement with the X-ray spectra observed by A. Westgren, A. Westgren and G. Phragmen, and E. C. Bain. The work of W. Rosenhain, and E. C. Bain also makes it difficult to assume the existence of large complex molecules of carbide in the space-lattice of γ-iron. A. M. Portevin and P. Chévenard, and K. Honda regard the doubling of the Ar-point as an effect of the special elements on the allotropic change ; and A. M. Portevin and P. Chévenard consider the lower point as one of labile equilibrium between a solid soln. of carbon in γ-iron (austenite) and a labile, solid soln. of carbon in α-iron. P. Dejean, and H. Scott regard the lower point to be the

$Ar_{3,2}$-arrest depressed by rapid cooling.   H. Hanemann and A. Schrader proposed an explanation based on the existence of a new modification of iron.

W. T. Griffiths assumed that nickel and chromium exert a double effect in retarding the γ- to α-change and in keeping carbon in soln.   In standard nickel-chromium steels the nickel is almost entirely in soln. in α-iron, the carbon is practically all present as carbide, and the chromium is almost entirely out of soln. as carbide.   In agreement with C. A. Edwards and co-workers, in steels with higher proportions of chromium some will be in soln. in the α-iron.   As the steel passes through the Ac-point, carbides pass slowly into soln., while the chromium and carbon diffuse outwards from the position of the carbide lattices.   In agreement with the observations of W. Rosenhain, E. C. Bain, and E. A. Owen and G. D. Preston on solid soln., the nickel and chromium atoms replace some iron atoms in the γ-iron lattice, distorting the lattice to some extent.   It is assumed that, owing to its small size, the carbon atom does not replace an iron atom, but is situated between the atoms of the face-centred lattice.   The effect of the substitution of nickel and chromium atoms for iron is to make the position of the carbon atoms more stable, and, in turn, the carbon atoms would tend to hold the iron atoms in their high temp. arrangement.

W. T. Griffiths continued : If the heating is interrupted just above the Ac-point, where dissolution and allotropic change are completed, very little diffusion will take place, and on slowly cooling the reverse change will occur to give the higher Ar'-point and a structure of pearlite and ferrite or cementite or complex carbide. If the heating be continued, diffusion will proceed further.   The rate of diffusion of the carbon will be higher than that of chromium, but not so high as in carbon steels, owing to the retarding effect of the nickel and chromium.   As the chromium diffuses, the combined stabilizing effect of the chromium and nickel on the carbon will spread, and the effect will probably increase with rise of temp.   Consequently, owing to the different rates of diffusion of carbon and chromium, the stability of the former will vary throughout the steel until a sufficiently high temp. or long period of soaking is employed.   On cooling, a different condition obtains just above the Ar'-arrest, for if the above effect has occurred throughout the whole steel, a much slower rate of cooling will be necessary to allow the γ- to α-change and the precipitation of the carbide ; while if the rate of cooling be fast enough, the whole mass may pass through the Ar'-point without any nuclei being formed on which recrystallization may occur.   E. W. Ehn discussed the effect of oxide and other impurities in providing nuclei for recrystallization.   If the steel is not homogeneous, with certain rates of cooling, in some areas the allotropic change will occur and carbide come out of soln.   Nuclei will thus be formed and recrystallization set in. Whether the recrystallization is completed or not will depend on the ratio of the rate of cooling to the velocity of crystallization, and the latter will also depend on the velocity of diffusion.   Hence, the change will occur in some parts of the steel, while others pass through the crystallizing range without change.   Hence, part of the recrystallization will occur at Ar', and the remainder completed at the lower temp. Ar''.   Again, if throughout the mass the conc. of nickel and chromium is sufficient for the rate of cooling, the whole of the steel will pass through the upper point without change.   Consequently, the proportions of carbon, nickel, and chromium required to depress the Ar-point are all interdependent ; so also are the effects of the initial temp., the time of soaking, and the rate of cooling.

W. T. Griffiths continued : If no recrystallization occurs at Ar' as the steel cools, the lattice will contract on itself, and the tendency to return to the more stable cube-centred lattice will increase.   A. F. Hallimond likened this steel to the metastable condition of supersaturated soln.   Finally, at a temp. depending on the proportions of nickel, chromium, and carbon, and on the rate of cooling, the lattice can no longer remain in the γ-state, and recrystallization will begin. The resulting product, as in the case of Ar', will depend on three factors—the temp. of the change, the rate of cooling, and the composition of the steel, for all

these alter the rate of diffusion and the rate of crystallization. Provided the rate of cooling is not excessively high, the iron will almost entirely change into the α-lattice. The carbon, being only slightly, if at all, soluble in this, will tend to diffuse from the changing areas, while some atoms will probably combine with neighbouring atoms to give Fe_3C-molecules. The chances of a carbon atom having a suitable number of chromium atoms in its neighbourhood to give either of the known chromium carbides will be remote. Molecules of iron carbide will almost alone be formed, and hence J. H. Andrew and co-workers found no chromium in the carbide residues from steels with small proportions of that element. The remaining carbon will tend to diffuse towards these nuclei and carry on crystal growth. If the temp. is sufficiently high in those areas which are lower in chromium content, the carbon, provided the rate of cooling is slow enough, will be able to diffuse at a sufficiently rapid rate to feed the growing crystals of carbide. If this rate of diffusion is not high enough, either by the rate of cooling being too rapid, or by the retarding action of the nickel and chromium, the carbon atoms will be trapped in the changing iron and martensite will be produced. In any case, it is unlikely that the crystals of carbide will grow to any large extent, and the high dispersion characteristic of troostite will be usual.

Observations on the Ar'-, Ar''-, Ar'''-arrests show that these temp. can be all represented on one curve, and it is doubtful if the Ar'''-arrest can be regarded as being the Ar''-point depressed by the high carbon content of the steels which show the phenomenon. W. T. Griffiths showed that carbon is probably the determining factor in the production of the Ar'''-point—at least, in steels of the comparatively low nickel and chromium content used commercially. Once the steel has passed through the Ar'-arrest without recrystallization, the carbon tends to hold the lattice in the high temp. arrangement, and its effect is relatively great. Also, J. H. Andrew and co-workers have pointed out the difficulty of obtaining the Ar'''-arrest with steels containing less than a certain percentage of carbon. Nickel and chromium, though they very easily produce depression of the point to the Ar''-arrest, are not so effective in giving an Ar'''-point when the carbon is low. A. M. Portevin and P. Chévenard have suggested that the duplicating of the lower point is due to the slowness of diffusion of the carbon after going into soln. Though it is probable that the effect is due partly to this, it does not explain why the change from Ar''- to Ar'''-arrest is so sudden, unless it be assumed that there is an initial pronounced non-uniformity in the steel. If this assumption cannot be made, it is possible that when the requisite percentage of carbon is present, on raising the temp. sufficiently above Ac, there is a further pronounced effect on the lattice, making it still more stable on cooling. What that effect is and how it is brought about is not known; it may be very tentatively suggested that if the carbon is initially in soln. in the way mentioned above, with higher carbon content and raised temp. some of the atoms may enter the γ-iron lattice and in this way produce a more stable arrangement. Initial temp. and time of soaking will affect the relative magnitudes of Ar''- and Ar'''-arrests in the same way as for Ar'- and the Ar''-arrests, that is, by regulating the amount of diffusion which will take place.

J. M. Robertson has made a study of the sequence of structures obtained when austenite is decomposed at progressively lower temp. He concluded that the ultimate composition of the decomposition products of austenite varies gradually as the temp. at which the transition takes place is lowered. When the transition takes place at the normal temp., the product consists of α-iron and cementite. As the temp. of the transition is lowered, more carbon is retained in soln. in α-iron, and less separates as cementite. The crystallographic form of the product of the decomposition of austenite depends on whether the decomposition is initiated by the allotropic change or by the formation of cementite. The Ar'-change is initiated by cementite, and the series of structures obtained at Ar' is determined by this fact. The Ar''-transformation is initiated by the allotropic change, and the structures formed at this change point are related to the crystallographic planes

of the austenite. The relations between the Ar'- and Ar''-points are determined by the fact that the allotropic change and the formation of cementite are differently affected by variations in the rate of cooling. The formation of cementite is slightly lowered, interrupted, and suppressed by a progressive increase in the rate of cooling. The allotropic change is progressively lowered as the rate of cooling is increased. The progressive lowering of the allotropic change cannot be realized in steels containing more than 0·2 per cent. of carbon, for in these steels, with certain rates of cooling, the decomposition of the austenite is initiated by the formation of cementite, and this change must be suppressed before the initiation of the transformation by the allotropic change can again be realized. In low-carbon steels, however, the structure passes directly from ferrite and pearlite to solid soln. structures, whose crystallographic form is similar to those produced when the Ar''-change in high-carbon steels takes place at a high temp. There are two series of structures produced by increasing the rate of cooling. Within each series the variation in structure is gradual. All structures formed at Ar'' may be tempered, and the tempered structure is related to the original structure, to the time, and to the temp. of tempering. The structures formed by cooling at different rates cannot be obtained by tempering other structures. So far as crystallographic form or structure is concerned, there is no relation between cooling at different rates and tempering at different temps. The same ultimate constitution may, however, be produced in either of two ways. When the α-solid soln. produced by very rapid cooling is reheated, carbon gradually separates from soln. and forms cementite. By reheating to different temp. all variations in constitution between solid soln. and ferrite-cementite aggregate may be obtained. Thus the globular structure, formed by tempering above 600°, may have the same ultimate constitution as the fan structure, but the crystallographic form and the general properties of these two structures are entirely different.

The dissolution of the pearlite by iron with a rising temp. was discussed by H. Jungbluth, etc. The sequence of changes which attends the cooling of iron or steel is more or less reversed as the temp. is raised—*vide supra*.

In 1786 L. B. G. de Morveau,[3] in his *Mémoire sur la conversion du fer en acier*, showed that *tout fer peut devenir acier* ; and he described his idea of the part played by carbon in converting iron into steel. He showed that carbon can exist in steel in two forms—*la plumbagine* (graphite) and *le charbon métallique* (iron carbide). J. R. Bréant also examined the steels microscopically, and classified steels into three groups according to the percentage of contained carbon. P. H. Berggren compiled a bibliography of the combinations of iron and carbon. As indicated in connection with the iron carbides—**5. 39, 20**—the finely-divided carbon which separates from white cast iron and certain steels during their prolonged annealing has some of the properties of graphite ; and, according to A. Ledebur, graphite is also formed by the rapid hammering of high-carbon steel at a red-heat. The graphite is insoluble in dil. acids. It is called **annealing** or **temper carbon**—or *carbon de recuit*—A. Ledebur's term, *Temperkohle, i.e. temper carbon*, is not so often used in England, because of the difference in meaning between the terms "tempering" and "annealing." The annealing or temper carbon in a sample of malleable cast iron is illustrated by J. E. Hurst's diagram, Fig. 130 (×200). There are three hypotheses as to the nature of annealing carbon : (i) C. James held that this carbon is a modification of graphite ; A. Lissner and R. Horny, that it is the same as iron graphite, since both forms have the same heat of combustion, but are in different states of subdivision ; and L. Northcott, that graphite and temper carbon are the same substance, but of different degrees of fineness ; (ii) A. Ledebur, that it is a carbide ; and F. Wüst, and H. von Jüptner, that it is amorphous carbon. F. Wüst and C. Geiger showed that chemically it behaves like graphite. J. W. Bolton recognized the following graphitic formations in cast irons : (i) broad, straight flakes ; (ii) rosettes or whorls ; (iii) dendritic striations ; (iv) grouped formations with clear, dendritic lakes and peninsulas

being filled with fine flakes; and (v) rounded temper carbon. K. Iokibe concluded from the X-radiograms that the so-called graphitic carbon and temper carbon occurring in cast iron are both the same substance as natural graphite—they give the same X-radiogram. The conditions of the decomposition of cementite are the same for both cast iron and steel, so that the temper carbon from carbon steels is also graphite, and not amorphous carbon. This conclusion is supported by the observations of G. Asahara, and F. Wever, and by other observations of L. Northcott, H. le Chatelier and S. Wologdine, A. Carnot and E. Goutal, G. Dillner, A. Pourcel, F. C. G. Müller, E. Donath, H. Wedding, E. Maurer and F. Hartmann, F. Mylius and co-workers, S. S. Knight, E. H. Campbell, H. Moissan, T. Turner, J. W. Bolton, A. Lissner and R. Horny, and H. Sawamura. Temper or annealing carbon usually occurs in the nodular form, while graphite is more or less flaky. Free **graphite** separates from highly carburized molten iron in the act of solidification. T. Millner, and H. A. Schwartz and co-workers studied the dissolution of cementite by acids. F. Wever found the particles of graphite from pig-iron, grey cast iron, temper carbon, coke, and charcoal all have the same lattice structure,
FIG. 130.—Annealing Carbon in Malleable Cast Iron (J. E. Hurst).
FIG. 131.—The Commencement of the Formation of Graphite at Several Centres in Cast Iron (J. E. Hurst).

showing that the carbon is the same allotropic form, but with different degrees of dispersion. The average size of the crystals of graphite from grey iron is 100×10^{-8} cm.; temper carbon, 30×10^{-8} to 50×10^{-8} cm.; and coke and charcoal, 10×10^{-8} cm. The lamellæ of eutectic graphite are ultra-microscopic in size. P. Debye and P. Scherrer said that the lattice of graphite is easily deformed by mechanical stresses, but F. Wever did not find this to be the case.

J. E. Hurst's diagram, Fig. 131 ($\times 200$), shows the formation of graphite in nuclei from the boundary of the chilled and grey portion of a sample of black-heart cast iron. The free carbon which separates from masses of molten iron by the dissociation of the carbide which separates in plates during the cooling of the molten grey cast iron down to the temp. of solidification is called **kish**—*Garschaum· graphit*—*vide supra*. B. Osann, and J. Freygang discussed the formation of kish in cast iron.

As previously indicated—**5.** 39, 5—carbon in the form of *diamonds* has been detected in some meteorites. L. Franck reported the formation of diamonds in hardened steel, and A. Ludwig, A. Rossel, H. Moissan, D. C. Tschernoff, E. Demenge,

and R. von Hasslinger discussed the formation of graphite, boart, and diamonds when iron saturated with carbon at a high temp. is suddenly cooled; and H. Fleissner, and P. Neumann discussed the formation of diamonds in the blast-furnace slags. The artificial synthesis of diamonds under these conditions has been questioned—**5**. 39, 5.

The dissolved carbon which confers hardness to steel when quenched from above the Ar_1-arrest is called **hardening carbon**—*Härtungskohlenstoff*, or *carbon de trempe*. The carbon in hardened and tempered steel which does not give a coloration when the steel is dissolved in nitric acid of sp. gr. 1·20 is sometimes called *missing carbon*—*carbone manquant*: The condition of the carbon as it occurs in iron tritacarbide or cementite is called *carbide-carbon*, or **combined carbon**. The term is also used to embrace all the various carbides in steels containing manganese, chromium, etc. The term *cement carbon* was applied by S. Rinman to the tritacarbide which remains undissolved at ordinary temp. when annealed steel is digested with dil. sulphuric acid in the absence of air. Hence, H. M. Howe called the tritacarbide, Fe_3C, **cementite**. Its microscopic appearance was described by H. C. Sorby. In the presence of manganese the cementite may contain manganese carbide; and silicon, and sulphur (*q.v.*) may also dissolve therein. The subject was studied by L. G. Knowlton, P. Pingault, and J. H. Andrew. A. Ledebur heated test-pieces of malleable iron to a medium red-heat and found the distribution of the different forms of carbon to be after

H. von Jüptner, and W. C. M. Lewis discussed the mol. wt. of the tritacarbide dissolved in iron. A. McCance calculated from the effect of carbon on the depression of the f.p. that the mol. wt. of the cementite in soln. is $(Fe_3C)_n$, where n is 2·03 at 1505° and 1·93 at 900°, so that the cementite between these temp. is dissolved as $(Fe_3C)_2$. A. Baykoff suggested that cementite is not really a definite compound, but rather a solid soln. This hypothesis is not supported by the available facts. The properties of the iron carbides are discussed **5**. 39, 20, and *vide supra*, pearlite. The thermal decomposition of cementite has been discussed above—*vide infra*, graphitization. Where ferrite and cementite are both present, the cementite is virtually unattacked by soln. of nitric or picric acid, tincture of iodine, etc., but it is darkly coloured by treatment with sodium picrate under conditions where pearlite remains bright.
FIG. 132. — Relative Proportions of Ferrite, Cementite, and Pearlite in Steels with Different Proportions of Carbon.

The cementite in normal steel with its eutectoidal proportion, 0·85 per cent., of carbon is all pearlitic; and with 6·7 per cent. of carbon it would be all cementite. In hypoeutectoidal steels it is present as lamellar pearlite along with masses of ferrite, and in hypereutectoidal steels it is present as lamellar pearlite along with masses of cementite. The cementite in excess of that associated with the eutectoid pearlite is sometimes called free, surplus, excess, massive, or proeutectoidal cementite, and similarly with free, surplus, excess, massive, or proeutectoidal ferrite. The relative proportions of free ferrite, free cementite, and pearlite in steels with different proportions of carbon are illustrated by Fig. 132. Calculations on this subject were discussed by H. P. Tiemann. As shown by J. O. Arnold and J. Jefferson, T. Andrews, W. G. McMillan, and F. Osmond

and W. C. Roberts-Austen, in general, during the solidification of a molten metal containing a trace of impurity, the particles of metal coalesce to form little islands of pure metal surrounded by a film of metal associated with impurity. In hypereutectic steels the pearlite behaves almost as if it were a pure metal, in that the excess of cementite may be rejected to the boundaries of the polyhedral grains so as to form a network of cementite with a ground-work of pearlite.

A. Sauveur measured by a planimeter the relative proportions of martensite, M, ferrite, F, and pearlite, P, in steels with 0·09, 0·21, 0·35, 0·80, 1·20, and 2·50 per cent. of carbon, quenched at different temp. Selecting the case of steel with 0·21 per cent. of carbon :

	880°	714°	698°	652°	620°	600°	559°	575°	200°
M	100	97·2	70·2	35·2	30·0	4·0	2·0	0·0	0·0 per cent.
F	0	2·8	29·8	64·8	68·4	78·5	75·8	78·9	21·1 per cent.
P	0	0·0	0·0	0·0	1·6	17·5	22·2	76·4	23·6 per cent.

E. H. Saniter, K. Honda and T. Murakami, G. Tammann and K. Ewig, A. L. Babochine, R. Ruer, and H. Sawamura discussed the stability of cementite at high temp.—*vide* **5**. 39, 20. The dissociation of cementite above 600° was studied by R. Horny, and the subject has been previously discussed in connection with the equilibrium diagram. The A_0-arrest with cementite also has been previously discussed. K. Honda referred to the A_0-arrest, where paramagnetic cementite becomes ferromagnetic, in these words :

This is the transformation characteristic of cementite ; it is in its nature the same transformation as the A_2-transformation with iron. The transformation is progressive and extends from the lowest temp. to 215°, the change being a definite function of temp. During heating or cooling, the transformation terminates or commences at the same temp., the A_0-arrest at 215°. This point is observable for all alloys containing free cementite, and it always has the same value.

According to S. Sekito, by tempering quenched steels at a gradually increasing temp. martensite begins to decompose at 200° and its decomposition is completed at 300°. In this stage the precipitated cementite is in a molecular or colloidal state, and does not form the space-lattice character-istic of cementite ; hence its spectral lines are so much diffused that they cannot be observed, as we have already seen ; but as the temp. is further raised, fine particles of cementite gradually coagulate and build up its space-lattice. Thus the spectral lines of cementite begin to appear at 300° on the X-ray film and increase in intensity up to 600°. The changes in the e.m.f. of steels tempered at about 380° are attributed to the formation of the cementite lattice from molecular or colloidal particles. The content of cementite can be roughly estimated from the intensity of the X-ray spectral lines, Fig. 133.

FIG. 133.—The Relation between the Proportion of Cementite and the Intensity of the X-Ray Spectral Lines.

N. G. Ilyine discussed the forms in which cementite appears in hypereutectic steels ; M. Sauvageot, the retarded dissolution and premature precipitation of cementite in eutectic and hypereutectic steels ; A. M. Portevin, proeutectoid cementite ; and H. M. Howe and A. G. Levy, H. C. H. Carpenter, and I. Iitaka studied the separation of cementite in hypereutectoidal steels in cooling from, say, 1200°. The line *ES* in the equilibrium diagram, Fig. 83, represents the progressive generation or separation of the cementite ; and the commencement of the curve is represented by what was called above, the A_{cm}-arrest. The A_{cm}-arrest occurs in hypereutectoidal steels, and marks the beginning of the separation of free cementite from austenite as the metal cools from A_{cm} to $A_{1,2,3}$. Except for the structural change no other marked changes in properties of the alloy have been connected with the A_{cm}-arrest. The austenite was shown by F. Osmond and

G. Cartaud, N. J. Wark, and A. Baykoff to be strongly oriented, for it has a marked crystalline structure. The coalescence of the excess or proeutectoidal cementite into visible masses is slow. The result with a steel with 1·45 per cent. carbon heated to 1200° and cooled to 745° and quenched is shown in Fig. 83 ; and the same steel heated to 1000°, cooled to 800°, and quenched is shown in Fig. 83. The coalescence of the internal cementite is slower than that which accumulates at the walls of the cells. The quantity of visible internal cementite increases to a maximum and then decreases. The decrease is occasioned by a transfer of cementite from the interior to the network—possibly by solution and re-precipitation. The apparent proportion of internal cementite is greater than is theoretically possible. This is an optical illusion ; what is taken to be wholly cementite may be in part pearlite. Most of the internal cementite is probably distributed in the cleavages of the austenite in which it is born, and it records the position of those cleavages after the austenite has suffered metamorphosis. Many of the spines which shoot from the network into the interior of the grains may not represent the austenite cleavages, but the orientation of the minute crystals which collectively make up the network as a dendrite. Increasing the proportion of carbon in the steel accelerates the
FIG. 134.—The Coalescence of Cementite FIG. 135.—Pearlite with Cementite
(H. M. Howe and A. G. Levy). Borders (H. M. Howe and A. G. Levy).

coalescence of the cementite. The coarseness of the network increases by raising the temp. and by increasing the proportion of carbon.

During the primary crystallization of the austenite foreign matter is rejected and driven to the surfaces of the crystals or collected along the cleavage planes. During the secondary crystallization of the grains of austenite free cementite, or free ferrite, is rejected, and as the pearlite grows it accumulates on the surface of the grains or along the cleavage planes. Hence, as observed by H. Brearley, the earlier formed slag may appear surrounded by the free ferrite or cementite which has been formed later. H. M. Howe pointed out that there is no need to assume that the common occurrence of slag in masses of ferrite is due to some attraction which the slag has for ferrite. H. M. Howe and A. G. Levy observed that if a hole is drilled in a block of hypoeutectoidal steel and closed to prevent the access of air, when the steel is heated above the transformation range and cooled slowly, the walls of the hole become covered with crystals of ferrite ; and with hypereutectoidal steel, with crystals of cementite. Analogous phenomena were observed by G. K. Burgess and co-workers. The expulsion of the excess ferrite or cementite in the pearlitic transformation of grains of austenite is paralleled by the presumed expulsion of graphite in making castings of malleable iron. For the metastability of cementite, *vide infra*, cementation. H. Kornfeld and G. Brieger studied the formation of cementite at the grain boundaries of mild steel.

A. Ledebur showed that the carbide existing in pearlite is chemically identical with that occurring as free cementite in the higher carbon alloys. P. Pingault obtained cementite of a high degree of purity by the action of sodium cyanide on electrolytic iron filings at 650°, and observed that the compound is stable in vacuo up to 1000° ; a slight decomposition occurs at 1075°, and complete decomposition at 1175°. G. Phragmen, however, said that general evidence indicates cementite to be more stable at elevated temp. than it is at lower temp. A. Westgren and G. Phragmen, S. Shigetaka, and F. Wever examined the X-radiograms of cementite and found that, like iron tritacarbide (q.v.), cementite crystallizes in the rhombic system, that four molecules are present in each space-lattice, and that the space-lattice has the dimensions $a=4\cdot518$ A., $b=5\cdot069$ A., and $c=6\cdot736$ A. The cementite of annealed steel, unannealed steel with lamellar pearlite, cast iron, spiegeleisen, and cohenite all gave the same X-radiogram. S. B. Hendricks studied the structure of the crystal lattice. For S. Shimura's observations, vide supra. T. Andrews gave 7·66 for the sp. gr. of cementite ; M. Levin and K. Dornhecker, 7·59 ; A. Westgren and G. Phragmen, 7·68 ; T. Ishigaki, 7·657 at 4° ; C. Benedicks, 7·74 and sp. vol. 0·1292 ; H. Moissan, 7·07 and sp. vol. 0·1414 ; and J. H. Andrew and A. J. K. Honeyman, 7·66 and sp. vol. 0·1306. A. Westgren and G. Phragmen gave 7·673 for the best representative value for the sp. gr., and 0·1304 for the sp. vol.— vide 5. 39, 20. Cementite is extremely hard and brittle ; it is the hardest of all the constituents of iron and steel. H. C. Boynton gave 272 for the hardness of cementite when that of ferrite is unity and that of martensite is 239—vide infra, hardness. K. Tamaru gave 720 for the Brinell's hardness of martensite and 620 for that of cementite, but when the cementite is strained its hardness may rise to 820. On Moh's scale the hardness of cementite is about 6·5, since it scratches felspar and not quartz. G. Charpy and P. Pingault found that after the carburization of iron filings to cementite, by heating them in contact with hydrocarbons or alkali cyanides, the product scratched glass and left no trace of graphite when dissolved in nitric acid. The cementite was stable when heated to 1000° for 10 hrs. in vacuo, and the heating curves showed no marked critical point. E. Scheil studied the effect of press. on cementite. L. Troost and P. Hautefeuille gave for the heat of formation $-20\cdot48$ Cals. per mol. ; and T. Watase gave $3Fe+C=Fe_3C-4\cdot8$ Cals. at 20°, and for the heat of combustion, $Fe_3+C+3O_2=Fe_3O_4+CO_2+366\cdot3$ Cals. at 20°. Y. Chu Phary studied the surface tension of cementite.

The eutectic with molten alloys of carbon and iron consists of a solid soln. of γ-austenite and cementite, vide supra ; the cementite is unstable at this high temp., 1130° ; and just as the cementite-ferrite eutectoid at the lower temp. has received the name pearlite, so has the austenite-cementite eutectic at 1130° received the name **ledeburite**—vide supra. Fig. 136 illustrates the ledeburite in iron with 4·3 per cent. of carbon. This subject was discussed by B. Osann, and H. Jungbluth.

Fig. 136.—The Microstructure of Ledeburite (J. E. Hurst).

In 1863 H. C. Sorby observed the polyhedral grains of what he called free iron in wrought iron; and H. M. Howe proposed the term **ferrite** be applied to α-iron free from carbon or containing only a trace of carbon in solid soln., when present in iron or steel. The term includes iron containing silicon, manganese, nickel, etc., which

form solid soln. with iron. Ferrite is the softest of all the constituents of iron or steel. Its microstructure is developed by etching with an alcoholic soln. of picric or nitric acid, when the outlines of the crystal aggregates appear to form polyhedral grains. The illustration of armco iron, Fig. 137 ($\times 150$ and reduced one-third), is due to W. J. Brooke and F. F. Hunting, and it shows that the ferrite is practically free from carbon and consequently also of pearlite. As indicated above, ferrite occurs in alternating layers with cementite in the pearlite of steels with 0·85 per cent. of carbon ; and any ferrite in excess of this is massive or free ferrite. Thus in Fig. 138 ($\times 250$), due to H. C. H. Carpenter, the polyhedral grains of the steel have here and there small, dark cells of pearlite. This steel had 0·048 per cent. of carbon, and was etched with a soln. of hydrochloric acid in amyl alcohol. When etched with nitric or picric acid, the ferrite of steels appears almost white. J. E. Stead reported crystals of ferrite 12·5 mm. across the major axis ; and A. Stadeler, crystals 7 mm. along the major axis, and they were visible to the naked eye. Observations on the structure and growth of ferrite crystals were made by H. S. Rawdon and H. Scott, C. Y. Clayton, E. Scheil, A. Hayes and H. E. Flanders, F. Giolitti and co-workers, N. T. Belaiew, and H. B. Pulsifer. V. N. Krivobok said that when cast hypoeutectoid steel is cooled and the temp.
FIG. 137.—Polyhedral Grains of Ferrite in Armco Iron.
FIG. 138.—Grains of Ferrite with a few Dark Cells of Pearlite ($\times 250$).

reaches the Ar_1-arrest, the austenite is decomposed ; part of the ferrite is rejected and part remains in soln. The rejection of the ferrite is favoured at the boundaries between the grains, and the ferrite thus forms a continuous mesh-work structure enveloping the outlines of the original grains of austenite. The inner structure is sorbitic, containing more ferrite than is required for the production of pearlite. If the cooling is slower, more ferrite is rejected, and the ferrite at the grain boundaries stimulates the rejection of more ferrite near or at the peripheries of the grains. This ferrite may either (i) join the ferrite at the boundaries so as to thicken the needle-like crystals, or (ii) be located between the cleavage planes of the grain, forming the so-called " shoots " of excess ferrite. These shoots or lamellæ of ferrite gradually fade away as they approach the interior of the grain. If the cooling be still slower, the rejected ferrite will assume more nearly the perfected form and appear on polished sections as a cleavage of Widmanstätten structure—*vide infra*—and in the extreme case occupy the whole grain. Even under conditions of very long and slow cooling the cleavage character of the structure will still remain. The ultimate structure, when no spheroidizing of the cementite or graphitization occurs, is a cleavage structure rather than the network. C. A. Edwards and T. Yokoyama discussed the effect of strains and various annealing temp. on the growth of crystals of ferrite.

C. A. Edwards said that the dark boundaries of the grains may be explained in three ways : (i) a differential etching set up by the interpenetration of the crystal units at the crystal junctions ; (ii) a differential etching between adjacent crystals of varying orientation ; and (iii) a selective etching away of the amorphous cement surrounding the crystals. The ferrite of steels is assumed to be almost pure iron, but in all probability a small amount of carbon is held in solid soln. C. Benedicks' observations on the sp. gr. and magnetic properties of steels indicated that the ferrite of steels with more than 0·5 per cent. of carbon differs from the ferrite of steels with a lower proportion of carbon. In the former case the ferrite has about 0·27 per cent. of carbon in soln., and in the latter case much less is dissolved, and the actual amount probably varies with the percentage of carbon in the steels. He applied the term *ferronite* to the ferrite in steels with over 0·5 per cent. of carbon. The hypothesis, however, has not been established.

O. W. Storey observed that when electrolytic iron is heated to 910° to 915°, the crystalline structure of the deposit is converted into the grain structure of ordinary ferrite, the grain-size being large or small according as the original deposit was coarse or fine, but no change occurred below the A_3-arrest. Coarse-grained ferrite became finer grained with a prolonged annealing at the A_3-arrest, but not so fine as that resulting from a fine-grained deposit. The grains of electrolytic iron do not grow appreciably at 1150°. The ferrite grains of fused electrolytic iron were composed of smaller grains, the boundaries of the latter being merely shallow depressions, whereas those of the former were V-shaped grooves. There was a continuity of the inner grain structure between merging grains of similar crystal orientation, and this inner structure was destroyed only by several annealings above the Ac_3-point. The inner grains were supposed groups of similarly oriented iron crystals, the orientation in all the grains being alike throughout the ferrite grain ; and the large grains of γ-ferrite formed during the slow cooling of the molten metal contain numerous similarly oriented nuclei—not γ-ferrite—and are changed to this state without altering in size. The microstructure of rolled electrolytic iron consists of clean ferrite ; and that of the forged metal, of fine-grained ferrite containing a minimum of impurities.

A distinct sub-crystalline structure, or veining, has been detected in certain grains of ferrite, by T. Andrews, F. Robin, J. C. W. Humfrey, W. Rosenhain and J. C. W. Humfrey, F. Sauerwald and co-workers, G. K. Burgess and J. J. Crowe, F. S. Tritton, and F. S. Tritton and D. Hanson. H. S. Rawdon and T. Berglund observed that the etching of α-ferrite reveals three types: α-veining, γ-network, and δ-network. The α-veining appears within the grains, giving a veined appearance to the α-ferrite as if it were fine-grained. Ferrite, stressed or forged at a temp. close to the $\alpha\gamma$-transformation, shows the α-veining very well; the presence of aluminium or manganese has no marked effect, but silicon suppresses this veining. The α-veining has no perceptible influence on the ordinary mechanical properties of ferrite. The γ- and δ-networks can usually be associated with tiny inclusions distributed in such a manner as to record the grain structure which existed in the high temp. allotropic states. The δ-network appears to be associated with the red-shortness of irons. E. Ammermann and H. Kornfeld found that the α-veining occurs throughout the ferrite grains of electrolytic iron only when the annealing temp. exceeds the A_3-point. Annealing between the A_1- and A_3-points produces local veining in those ferrite grains in close proximity to the cementite or pearlite fields, probably owing to a local reduction of the A_3-point by the segregation of the carbon. Deformation below the A_3-arrest does not produce veining unless the metal is subsequently annealed above this point, in which case the deformed metal has the veining more marked than is the case with metal which has been simply annealed without deformation.

According to C. O. Bannister and W. D. Jones, the veinage of α-ferrite grains is a manifestation of microscopical or sub-microscopical inclusions in the metal. In some cases, at a previous state of crystallization these inclusions would for the most part have been situated at the normal crystal boundaries, but following

certain mechanical and thermal treatments, crystal growth has occurred, and ·the inclusions have not been of sufficient magnitude to prevent growth, although they have been sufficiently definite to be capable of being shown up by suitable etching operations. Summarizing the available evidence, C. O. Bannister and W. D. Jones say :

A.—The *a*-veining may be expected to be produced in iron and low carbon steel containing microscopical or sub-microscopical inclusions, or containing impurity in solid soln. which is liable under certain conditions to be precipitated as inclusions by any thermal treatment which (1) causes recrystallization or crystal growth; or (2) induces inclusions to segregate at boundaries, either as definite inclusions, or as inclusions in soln., which may be subsequently precipitated.

B.—The *a*-veining may be expected to be destroyed by treatment which (1) promotes the re-solution of the inclusions when soluble; or (2) causes the re-distribution of insoluble inclusions, as by (*a*) hot or cold-working, (*b*) recrystallization after heating to a high temp., or (*c*) quenching after certain heat treatments and from certain temp., depending on the nature of the inclusions.

C.—The *a*-veining may be expected to be absent in (1) very pure materials containing no non-metallic inclusions; (2) portions or definite crystals of a less pure material which are free from non-metallic inclusions; or (3) less pure materials in which the conditions have been such that any inclusions are held in solid soln.

§ 16. Heterogeneous Alloys

T. W. Hogg [1] examined the metal taken from different parts of a mild steel ingot weighing about 11 tons, and found the impurities collect in the central core, where solidification is slowest. The phenomenon is similar to that observed in the freezing of water, where impurities are rejected by the first crystals of ice which are formed—**1**. 10, 2. M. Stevens found that, with cast iron from the blast-furnace, the silicon accumulates near the middle of the cast, amounting to 2·92 per cent. near the middle, 1·58 per cent. at the beginning, and 1·80 per cent. at the end of the cast. Phosphorus follows the silicon, but sulphur and manganese do not vary greatly.

A. Pourcel said that the average order of segregation during solidification in iron and steel is : carbon, phosphorus, sulphur, silicon, and manganese. Copper segregates quickly, but homogeneity is imparted by the addition of aluminium. Chromium and tungsten steels are liable to segregation, but not so with nickel steels. J. E. Stead said that sulphur segregates most, then phosphorus, and then carbon, whilst manganese and silicon do not segregate to any material extent ; and F. Wüst and H. L. Felser, that the tendency of sulphur and phosphorus to segregate is greater than that of carbon, copper, and manganese. H. Rubricius noted that silicon tends to accumulate near the bottom of the blast-furnace. W. Hampe found ferro-manganese from four levels in the furnace had 82·82, 81·97, 81·10, and 80·17 per cent. of manganese. E. Piwowarsky observed that samples of mild steel which had been deoxidized with aluminium or with ferrovanadium developed a structure on annealing in which the ferrite had segregated in wide-meshed networks enclosing areas of pearlite, and in some cases large ferrite areas were distributed irregularly through the specimens. Similar steels deoxidized with ferrosilicon and cast without a deoxidizing agent developed the usual dendritic ferrite structure on annealing.

B. Talbot, R. W. Hunt, and G. F. Comstock said that aluminium prevents segregation, but, according to N. Lilienberg, it does not prevent piping. G. B. Water-house observed that titanium retards the segregation of sulphur, phosphorus, and carbon ; and the subject was discussed by M. C. Smith, N. Petinot, and E. F. Lake. According to H. M. Wickhorst, silicon lessens segregation but increases piping. H. M. Boylston compared the effects with silicon, titanium, manganese, and aluminium ; T. Swinden, manganese, silicon, and aluminium ; G. K. Burgess and G. W. Quick, silicon and titanium ; and G. F. Comstock, aluminium and titanium. The Soret effect in alloys was observed by M. Ballay, A. W. Porter, and C. C. Tanner ; and segregation after solidification, by G. d'Huart, C. Benedicks, and A. Lundgren.

Segregation in steel castings was observed by L. Aitchison, J. H. Andrew and co-workers, T. Andrews, J. O. Arnold, P. Bardenheuer and co-workers, O. Bauer, O. Bauer and H. Arndt, G. Belloc, T. Berglund, R. Bolling, A. W. and H. Brearley, H. Brearley, A. Brüninghaus and F. Heinrich, R. H. Canfield, H. le Chatelier and co-workers, G. Charpy and S. Bonnerot, C. Y. Clayton and co-workers, J. J. Cohade, G. F. Comstock, M. Demole, J. Descolas and E. Pretet, M. T. Denne, W. Dinkler, T. M. Drown, P. H. Dudley, H. Fay, J. E. Fletcher, C. Frémont, J. D. Gat, F. P. Gilligan and J. J. Curran, F. Giolitti, R. A. Hadfield, H. Hanemann and O. Schröder, H. Harmet, J. Henderson, E. Heyn and O. Bauer, H. D. Hibbard, V. O. Homerberg, H. M. Howe and co-workers, H. G. Howorth, G. d'Huart, J. C. W. Humfrey, R. W. Hunt, C. L. Huston, K. Iokibe, J. E. Johnson, H. von Jüptner, E. F. Kenney, O. von Keil and A. Wimmer, S. S. Knight, W. E. Koch, A. Kriz, A. Ledebur, M. Levitzky, A. W. Lorenz, H. W. McQuaid and E. H. Ehn, E. G. Mahin and co-workers, G. Masing, A. Messerschmitt, H. Meyer, C. A. Müller, W. Oertel and L. A. Richter, P. Oberhoffer, B. Osann, F. Osmond, N. Petinot, L. Pichard, A. M. Portevin and co-workers, R. Powell, W. J. Priestley, H. B. Pulsifer, H. S. Rawdon, E. L. Reed, H. Reuss, J. Reimer, C. H. Ridsdale, A. Ruhfus, B. D. Saklatwalla, E. Scheur, E. H. Schulz and J. Goebel, F. Sommer and F. Rapatz, A. Stadeler and H. J. Thiele, J. E. Stead, H. Styri, P. Tabary, G. Taguéeff, B. Talbot, E. E. Thum, D. K. Tschernoff, T. H. Turner, M. Viteaux, A. Wahlberg, E. Walldow, G. B. Waterhouse, W. R. Webster, P. Weiller, T. D. West, B. F. Weston, A. E. White, J. H. Whiteley, and F. Wüst and H. L. Felser. A. Schleicher, J. Hanny, P. Oberhoffer, J. J. Cohade, C. S. Crouse, E. H. Schulz and J. Goebel, F. Sommer and F. Rapatz, H. Styri, E. E. Thum, F. Giolitti, C. Y. Clayton and co-workers, and H. S. Rawdon discussed *flaky steel*, and *flaky fractures* ; F. C. Thompson and R. Willows, *banded steel*.

The *piping* of steel ingots was discussed by F. O. Beikirch,[2] H. Brearley, A. Brüninghaus and F. Heinrich, C. Canaris, G. Charpy, R. M. Daelen, A. Diefenthaler, P. H. Dudley, F. L. Enquist, G. Tammann and H. Bredemeier, J. E. Fletcher, J. D. Gat, H. M. Howe and co-workers, E. F. Kenney, W. Claus, H. Kusl, N. Lilienberg, B. Osann, D. K. Tschernoff, and H. Wedding.

The *inclusions* in iron and steel—slag, manganese, and iron sulphides, silicates, and oxides, phosphates or phosphides of calcium, magnesium, manganese, and iron, titanium nitride, alumina—were discussed by E. Ammann,[3] J. H. Andrew, T. Andrews, J. O. Arnold and G. R. Bolsover, A. Baikoff, O. Bauer, C. Benedicks and H. Löfquist, F. Bondolfi, H. Brearley, A. Campion, G. F. Comstock, E. J. Cook, J. H. S. Dickenson, J. W. Donaldson, W. Eilender and W. Oertel, H. Fay, F. Fischer, G. R. Fitterer, I. S. Gaieff, J. D. Gat, W. H. Gillet, F. Giolitti and co-workers, S. L. Goodale and P. H. Kutar, P. Goerens, L. E. Grant, W. H. Hatfield, F. Hartmann, C. H. Herty and co-workers, H. D. Hibbard,

H. G. Howorth, G. d'Huart, A. Hultgren, C. Johns, H. Kjerrman, J. N. Kilby, A. B. Kinzel and W. Crafts, E. Kothny, S. Kriz and H. Kral, B. M. Larsen, E. F. Law, A. McCance, E. G. Mahin, G. Mars, M. Matweieff, P. Oberhoffer and co-workers, F. Pacher, J. A. Pickard, J. A. Pickard and F. M. Potter, W. J. Priestley, H. S. Rawdon, G. Röhl, A. Sauveur, C. E. Sims and G. A. Lillieqvist, M. C. Smith, A. Stadeler, J. E. Stead, S. Steinberg, L. Treuheit, J. H. Whiteley, A. Wimmer, C. R. Wohrmann, F. Wüst and N. Kirpach, and W. Zieler. G. Tammann and W. Salge studied the residues left after treating the metal with an acidified soln. of ammonium persulphate.

The *blowholes* in iron and steel ingots due to the escape of occluded gases were discussed by T. Andrews,[4] T. Baker, G. Belloc, H. Brearley, G. Charpy, J. W. Donaldson, C. H. Desch, W. Eichholz and J. Mehovar, J. Goebel, P. Goerens and J. Paquet, E. Goutal, P. L. T. Hérault, H. D. Hibbard, H. M. Howe, K. Iwase, O. von Keil and A. Wimmer, P. Klinger, W. Kusl, A. G. Lobley and C. L. Betts, E. von Maltitz, P. Oberhoffer and co-workers, N. Parravano and A. Scortecci, A. Ruhfus, J. E. Stead, T. C. Sutton and H. R. Ambler, K. G. Troubine, D. K. Tschernoff, H. Wedding, and A. Wimmer.

§ 17. The Crystallization of Iron and the Iron-Carbon Alloys

The formation of the first germs of crystallization is one of the most important phenomena among the many occurring during the solidification of molten alloys. The properties characteristic of the solid alloy depend to a very large degree upon the number of centres of crystallization and the cause of their formation. So strongly, in fact, does this state of affairs impress itself on the metal, that the vestiges remain even after all the heat treatment and mechanical work to which it will be afterwards subjected.— F. GIOLITTI.

The polyhedral—πολύεδρος, with many sides—network, meshed or cellular structure of iron, Figs. 137 and 138, bears no relation to its internal symmetry,

and, as pointed out by C. H. Desch,[1] it represents a compromise between the opposing forces of crystallization and surface tension in the later stages of the solidification of the metal. The study of the homogeneous partitioning of space to form cells with the minimum superficial area furnished E. Fedoroff with a cubo-octahedron which he called a heptaparallelhedron ; and Lord Kelvin, with a similar cell which he called the tetrakaidecahedron. The actual shape of the cell produced by the crystallization of a molten metal is, of course, modified by the crowding of the growths. The space needed for the development of one crystal may be already occupied by other crystals. Crystals which have taken the shape imposed on them by their environment are called **allotrimorphic crystals—** ἀλλόντρος, strange ; μορφή, form—whereas those which have developed their characteristic external form are called **idiomorphic crystals—**ἴδιος, peculiar ; μορφή, form. This subject was also discussed by V. M. Goldschmidt, N. T. Belaiew, L. Cammen, L. Gruardet, and L. Baclé.

The early workers noticed that iron has a crystalline structure. F. Wöhler obtained cubic crystals by breaking plates of cast iron which had been exposed to a white-heat in the brickwork of an iron smelting-furnace, and he also obtained octahedral crystals in the cavities of a large cast iron roll. M. Augustin also reported cubic crystals on the fractured surfaces of gun-barrels which had been long in use. J. Percy also found cleavage planes of crystals arranged perpendicularly to the surface of an iron bar which had been standing for a long time in molten glass ; while W. H. Miller said that iron prepared by the Bessemer process is an aggregate of small cubic crystals. The crystals are very imperfect in consequence of their not having had room to develop their faces. Some of them have measurable angles, approximating 90°. The amount of impurity present was considered too small to be likely to have affected the crystalline structure. W. H. Hatfield showed that the structure of steel ingots after solidification results in (i) a thin external zone with a very fine, almost amorphous, crystalline structure which acts as an outer envelope of the ingot, and it is formed by the abrupt cooling, during the pouring of the steel, by contact with the cold walls of the mould ; (ii) an intermediate zone consisting of elongated dendrites having their axes perpendicular to the walls of the mould ; and (iii) a central zone consisting of globular crystals having equal perpendicular axes. The crystallization of cooling ingots was studied by W. H. Hatfield, B. Matuschka, and C. Schwarz. V. N. Krivobok and O. E. Romig noted the absence of any relation between the surface structure of cast metals and the internal crystalline structure.

G. Tammann and A. A. Botschwar observed that when a fine ray of light is passed through a pin-hole in a piece of photographic paper on to an etching pit in a deeply etched crystal surface of copper or iron a light figure is reflected on to the paper in a form characteristic of the orientation of the crystal and of the angle of incidence of the light. When the incident ray is perpendicular to the reflecting surface an octahedral plane produces a figure composed of three intersecting lines of equal length at an angle of 120° to one another, a cube plane gives a " webbed " cross, and a rhombic dodecahedral plane a straight line.

G. W. A. Kahlbaum obtained microscopic hexahedral crystals by sublimation ; and A. C. Becquerel, by electrolysis, as indicated in connection with the preparation of iron. J. A. Poumarède prepared dendritic iron frequently in the form of hollow tetrahedra, by reducing ferrous chloride by zinc vapour ; and E. Péligot obtained octahedral crystals and W. Haidinger, hexahedral crystals by reducing ferrous chloride in hydrogen. E. F. Lange described the so-called furnace crystals of carbonless or almost carbonless iron occasionally found in furnace hearths or slag masses. The analysis of crystals from the pocket in the hearth of a steel furnace gave no combined carbon or manganese, a trace of silicon, 0·02 per cent. sulphur, 0·36 per cent. phosphorus, and 99·62 per cent. iron. The external appearance of the metal resembled a mass of crystal surfaces, mostly pentagonal, with smooth, flat faces, some being of considerable size. Their formation is due to the constant

growth of the granules under the combined influence of time and heat; and the effects of expansion and contraction upon groups of such granules in their plastic condition produce the forms of pentagonal dodecahedra such as are produced by the compression of plastic spheroids. This would be helped by the liquation of the more fusible phosphide of iron between their cleavage planes. On breaking up the mass when cold, the lines of fracture would be along the brittle films of the phosphide, thus clearly revealing the formation produced under the above circumstances.

References to the crystalline structure and the metallography of iron and steel were also made by T. Andrews, W. Armstrong, J. O. Arnold, J. A. Aupperle, C. O. Bannister and W. D. Jones, A. Beardsley, H. Behrens, C. Benedicks, G. V. Bianchetti, H. Braune, P. Breuil, R. von Carnall, A. T. Child and W. P. Heineken, W. Crookes, J. Czochralsky, M. Desfosses, G. Dillner, E. F. Dürre, J. A. Ewing, K. Faller, H. Fay and co-workers, T. B. Focke, C. W. C. Fuchs, J. N. von Fuchs, F. Giolitti, R. Glocker, P. Goerens, L. Gruardet, A. Greiner, P. C. Grignon, J. Grone, L. Guillet, E. F. Gurlt, J. F. L. Hausmann, W. Heike and W. Brenscheidt, F. Hermann, E. Heyn, S. A. Houghton, H. M. Howe, O. F. Hudson, O. W. Huntington, C. L. Huston, Z. Jeffries, J. H. B. Jenkins and D. G. Riddick, J. E. Johnson, L. M. Jordan, H. von Jüptner, F. Kerdyk, S. S. Knight, C. Kohn, M. Kralupper, A. Kroll, R. Kühnel, C. F. Lan, P. Lejeune, G. E. Linck, N. N. Ljamin, P. Longmuir, W. von Möllendorff and J. Czochralsky, R. Moldenke, L. B. G. de Morveau, D. Mushet, J. J. Nöggerath, J. Parry, P. M. Partsch, A. M. Portevin, M. A. F. Prestel, F. S. Rice, C. H. Ridsdale, J. B. L. Romé de l'Isle, W. von Rüdiger, A. Sadebeck, A. Sauveur, J. von Siemachko, W. C. Smeaton, A. Stansfield, S. Stein, J. von Sternberg, B. Stoughton, F. Ulrich, and H. Wedding. A. L. Colby compiled a bibliography of the subject. For the structure of electrodeposited metal, *vide supra.*

The granular structure of steel, as evidenced by the formation of irregularly-shaped, polygonal masses, devoid of any definite crystalline form, was discussed by D. K. Tschernoff, J. A. Brinell, H. C. Sorby, A. Martens, J. O. Arnold, T. Andrews, J. E. Stead, U. Savoia, A. Sauveur, P. Kreuzpointer, A. E. Seaton, W. E. W. Millington and F. C. Thompson, L. Baclé, L. Gruardet, etc. F. Leitner found that the size of the primary crystallites is dependent on the fluidity and casting temp. of the metal. F. Osmond said :

Iron is a mass of globules, more or less welded, which present an apparent tendency to group themselves in margarites and layers. Its mass is subdivided into jointed polyhedrons. When the temperature has not been too high, these forms are regular enough, and one can easily recognize in them those of the pentagonal dodecahedron. Are the polyhedrons in question crystals or grains ? Are their surfaces of contact cleavages or joints ? The answer does not appear to me to be doubtful. The mass may be crystalline, but the envelopes are not. Forms exactly similar are obtained by synthesis, by compressing plastic spheroids in a mould. The desiccation of damp pastes and the solidification of melted materials equally produce analogous divisions.

H. Wedding said that other things being equal, the size of the grains increases with the slowness of the cooling, but with the same kind of cooling and with proportions of carbon up to 2 per cent., the size of the grain decreases. Above this amount the size of the grains increases. Silicon, sulphur, small proportions of manganese, titanium, chromium, and tungsten favour small grains, while phosphorus increases their size. R. M. Bozorth discussed the orientation of the electrodeposited crystals.

J. E. Stead observed that when steel is heated in lime for a few hours at 700° or 800°, the metal is partially decarburized, and the crystal grains assume a columnar formation ; and a similar phenomenon was observed in the decarburization of malleable cast iron, for the crystal grains were found to be arranged in columns radiated inwards from the exterior. C. R. Austin found that in the decarburization of steel by hydrogen the columnar formation appeared. He concluded that carbon-free iron does not form the columnar structure by any simple heat treatment ; this structure is not developed if the steel is annealed in a non-oxidizing environment ; nor is it developed by the diffusion of carbon from a high-carbon steel to pure iron when the two are brought in contact and

annealed together. It is developed only when the carbon is removed by oxidizing agents from the surface at a temp. below 850°.

J. E. Stead and H. C. H. Carpenter found that when electrodeposited iron of a high degree of purity—0·008 per cent. carbon and 99·967 per cent. iron—is heated above the Ac_3-arrest and then cooled below the Ac_3-arrest, it furnishes a coarsely crystalline structure with the crystals sometimes equiaxial and sometimes radial, or both. They are both probably α-iron. These effects are produced with plates with a thickness between 0·009 and 0·012 inch. The coarse crystals are destroyed by cold mechanical work ; by heating above the Ac_3-arrest and quenching ; or by a prolonged heating above this temp. followed by slow cooling. The heat treatment that produces coarse crystals in electrodeposited iron refines wrought iron and very mild steel that have been rendered coarsely crystalline by close-annealing between 700° and 800° ; but annealing at 700° to 800° has no effect in coarsening the structure of electrodeposited iron which has been refined by cold mechanical work.

C. A. Edwards and L. B. Pfeil studied the conditions under which large single crystals can be obtained, and, by modifying H. C. H. Carpenter and C. F. Elam's process for aluminium, produced single crystals by annealing deformed crystals of purified iron just below the Ac_3-arrest. E. Sütter found that large crystals could be obtained by electrolysis ; and that crystals could be grown on iron or tungsten wires heated to redness in the vapour of ferric chloride. Observations on this subject were made by W. Gerlach, E. Dussler and W. Gerlach, K. Honda and co-workers, W. L. Webster, E. B. Wedmore, J. A. M. van Liempt, E. Sütter, M. Privault, J. Seigle, P. W. Bridgman, W. E. Ruder, H. Griess, H. Griess and H. Esser, C. F. Elam, R. Glocker, and N. A. Ziegler. L. B. Pfeil, F. Wever, G. Tammann and A. Müller, and L. W. McKeehan prepared long single crystals of iron by allowing an electrically heated portion, at 1400°, to move along the wire. Irregular tension and torsional stresses result in twinning.

F. Osmond and co-workers reduced ferrous chloride by hydrogen and by zinc vapour, at different temp., and concluded that all three allotropic forms of iron—α-, β-, and γ-iron—crystallize in the cubic system. The crystals were all small, but there was an element of uncertainty, for H. le Chatelier suggested that the results for γ-iron might be explained by the assumption that the crystals are rhombohedra simulating a cube. H. Wedding stated that the presence of over 2 per cent. of manganese changes the regular crystal form of iron containing carbon into crystals belonging to some system other than the cubic—probably rhombic ; but H. Bauerman did not accept this statement, in view of A. Erman's observation that the ferromanganese of the Urals is cubic with a rhombic habit, and E. Mallard's observation that 11 to 52 per cent. ferromanganese crystallizes in the tabular form, with a prism of about 112°, and with more manganese the structure becomes acicular owing to the aggregation of six-sided prisms of about 120°. In confirmation of the cubic form, J. E. Stead showed that by strongly etching purified iron, or iron containing much phosphorus, crystals apparently in the form of square plates are readily developed—vide Fig. 14, 1. 11, 4. In mechanical tests with micro-sections, such of the grains as are built up of crystals with cleavages at right angles to the surface break up and fracture in two directions at right angles to one another, in agreement with the assumption that the crystals are cubic. Cubical

FIG. 139.—Cubic Crystals of α-iron (J. E. Stead).

forms obtained by splitting up a large granule of phosphoretic iron through the cleavage planes are shown in Fig. 139 (× 5). In general, iron forms cubic, octahedral, or trapezohedral crystals. The cube is the characteristic form of α-iron or ferrite. This is shown by the strongly marked cleavage ; by the course of Neumann's bands and slip-bands—*vide infra* ; and by the cleavages of some meteoric iron. The octahedron is the characteristic form of γ-iron and austenite. This is shown by the twinning planes, the slip-planes, and the Widmanstätten figures. The trapezohedron is revealed by the course of the Neumann bands and the slip-bands. The crystalline forms of the different known varieties of iron have been definitely settled by the X-radiograms. A. Westgren and co-workers showed that the X-radiograms of α-, β-, and δ-iron correspond with a body-centred cubic lattice, whilst the X-radiogram of γ-iron corresponds with a face-centred cubic lattice. Observations on the X-radiograms and on the atomic structure of the crystals of iron and steel were made by G. Tammann and A. A. Botschwar, K. Heindlhofer, D. H. Killeffer, R. Schenck, E. Schmid, R. Berthold, F. Rinne, H. Shoji, O. L. Roberts, A. Smekal, G. L. Clark and co-workers, J. H. Andrew, K. Weissenberg, O. Mügge, F. Roll, A. Karlsson, W. Rosenhain, R. Bach, F. Kirchner, and R. W. G. Wyckoff. W. E. Williams discussed the structures of hardened and tempered steels obtained by X-radiograms. M. C. Neuburger has a monograph : *Röntgenographie des Eisens und seiner Legierungen* (Stuttgart, 1928). W. Hume-Rothery discussed the relations amongst the lattice constants of iron and other elements ; and W. L. Fink and E. D. Campbell, the effect of heat treatment and carbon content on the lattice. J. Forrest discussed the magnetic lattice ; and U. Dehlinger, the electron entropy of the transition forms of iron.

R. Bach emphasized the fact that from room temp. up to the m.p. there are really only two allotropic forms of iron, (i) with the body-centred lattice and including the α-, β-, and δ-varieties, and (ii) the face-centred lattice or γ-iron. He measured the effect of temp. on the lattice constant, a, of 99·46 per cent. iron, and found for the percentage values da/a at

	730°	785°	830°	860°	885°	900°	1370°	1400°
a	2·9004	2·882	2·9071	2·9043	3·653*	3·655*	3·688*	2·9347 A.
da/a	1·06	1·02	1·29	1·19	1·02	1·08	2·01	2·25 per cent.

The results are plotted in Fig. 140. The * denotes γ-iron. A. E. van Arkel and W. G. Burgers observed that the lattice constant, a, for the purified oxide reduced by hydrogen is 2·8614 A. ; for electrolytic iron, 2·8614 A. ; for cast steel, 2·8623 A. ; and for steels with 1, 12, and 25 per cent. of chromium, respectively 2·8635, 2·8666, and 2·8675 A. The α- and δ-varieties are considered to be the same owing to the continuity of the thermal expansion curves. In the interval between 900° and 1400° the expansion curve of γ-iron runs parallel to the continuation of the curve for

FIG. 140.—The Effect of Temperature on the Lattice Constants of Iron.

β-iron. The contraction represented by the passage of α- to β-iron is greater than that which can be attributed to the disappearance of spontaneous magnetization, and it is doubtful if the α-state can be distinguished from the β-state uniquely by magnetic differences. P. P. Ewald and C. Hermann summarized the data as in Table XIII.

A. W. Hull found that the space-lattice of α-iron is a body-centred cube with side $a=2·86$ A., and W. P. Davey gave $a=2·858$ A. for the lattice constant of purified iron, and 2·585 for iron with 0·020 per cent. of carbon, 0·017 of sulphur, and 0·021

TABLE XIII.—LATTICE CONSTANTS OF IRON CRYSTALS.

	Lattice	Temperature	Parameter a	Shortest distance between atoms	Atomic volume
a-iron	Body-centred	16°	2·86 A.	2·477 A.	11·7
β-iron	Body-centred	800°	2·90 A.	2·513 A.	12·2
γ-iron	Face-centred	1100°	3·63 A.	2·57 A.	12·0
δ-iron	Body-centred	1425°	2·93 A.	2·538 A.	12·6

of silicon; he also gave $2·472 \times 10^{-8}$ cm. for the closest approach of the atoms. F. Wever showed that the a-lattices for electrolytic iron and for annealed steels with 0·07, 0·56, and 0·86 per cent. carbon all gave the same lattice parameter, $a = 2·863 \times 10^{-8}$ cm.; E. A. Owen and G. D. Preston gave $a = 2·869$ A. for the body-centred cubic lattice; L. W. McKeehan, $a = 2·872$ A.; G. Mayer found for a-iron obtained from iron carbonyl, $a = 2·86106$ A. at 22°; A. Osawa, $a = 2·865$ A. at 15°; A. Westgren and A. E. Lindh, 2·87 A. for a-iron, and 2·92 A. for β-iron; A. Westgren and G. Phragmen, 2·87 A. for a-iron at 16°; 2·90 A. for β-iron at 800°; and 2·93 A. for δ-iron at 1425°; F. C. Blake, 2·8603 A.; R. Brill and H. Mark, and O. Eisenhut and E. Kaupp, 2·863 A. The shortest distance apart of the atoms of a-iron was estimated by A. Goetz to be 2·512 A., when $a = 2·90$ at 900°. H. Perlitz discussed the subject.

A. Westgren and A. E. Lindh found the parameter a of the space-lattice of γ-iron at 1000° to be 3·60 A.; A. Westgren and G. Phragmen gave at 1100°, $a = 3·63$ and at 1425°, 3·68 A.; F. Wever, 3·56 to 3·60 A.; and A. Goetz, $a = 3·59$, and the shortest distance of the atoms apart is 2·539 A. For austenitic steel with 25·2 per cent. of nickel, A. Westgren and A. E. Lindh gave $a = 3·58$ A.; for austenitic steel with 12·1 per cent. of manganese, $a = 3·61$ A., and A. Westgren and G. Phragmen gave 3·61 A. for the 12·1 per cent. manganese steel. E. Oehman gave $a = 3·562$, and for the shortest distance apart of the atoms, 2·52 A.—vide infra, the iron-manganese alloys. F. Wever gave for austenitic steel cooled in liquid air $a = 3·565$ A., for the same steel partially converted into martensite, $a = 2·849$ A., and for the same steel after cold-working, $a = 2·839$ A.; and F. Wever and P. Rütten observed that the lattice constant for γ-iron containing carbon in solid soln. expands linearly 0·006 to 0·007 A. per atom of carbon; and A. Osawa obtained a similar result with nickel steels. A. Westgren and G. Phragmen gave for the γ-iron lattice for carbon steel quenched from 1000° and 1100°:

Quenched from		1000°			1100°	
Carbon	0·24	1·18	1·98	0	1·98 per cent.
a	3·56	3·64	3·64	3·63	3·65

According to F. Wever, the lattice parameter for a-iron is 2·861 A., and it is not affected by the presence of carbon in the annealed alloy, and there is only a slight increase in the hardened alloy. This all shows that the carbon here is mainly occupied in filling spaces in the lattice. On the other hand, the lattice parameter for γ-iron in austenitic steels increases directly with the carbon content and the manganese content in accord with $3·578 + 0·0005[Mn] + 0·00645[C]$, where the bracketed symbols represent atomic percentages. This is taken to mean that these elements replace iron in the lattice.

K. Honda and S. Sekito consider that in the case of austenite the carbon atoms are distributed according to the law of probability at the centre of an elementary cube; whilst in the case of martensite the carbon atoms are distributed according to the law of probability in the centre of the face of an elementary cube. The observations of W. L. Fink and E. D. Campbell, M. Majima and S. Togino, N. Seljakoff and co-workers, G. Kurdjumoff and E. Kaminsky, K. Honda and co-workers showed that in quenched steel the surface layer contains a body-centred

tetragonal lattice with the axial ratio $c : a = 1.06$, as well as a small quantity of retained austenite with a face-centred lattice. K. Honda and S. Sekito identify this with α-martensite—*vide supra*, martensite ; and *vide infra*, hardening.

A. Osawa noticed that the edge-length of a unit cell of α-iron increases with temp. as iron expands on heating. A. Westgren and co-workers observed that while $a = 2.87$ A. at 800°, it becomes 2·90 A. at 1425°. It was also found that the so-called β-iron, between 800° and 830°, has the iron atoms oriented in exactly the same way
FIG. 141.—Space-lattice of α- and δ-irons.
FIG. 142.—Space-lattice of γ-iron.

as those of α-iron : and hence, on the assumption that allotropy and polymorphy are synonymous terms, it was inferred that β-iron is not truly a definite modification of iron—*vide supra*. It was also found that γ-iron, at 1100°, has a face-centred cubic lattice with sides $a = 3.61$ A. The results are summarized in Figs. 141 and 142. Assuming that the crystals are made up of spherical atoms, an imitation of the body-centred packing is given in Fig. 143, and of the face-centred packing in Fig. 144. Since δ-iron at 1400° has a body-centred cubic lattice, it follows that
FIG. 143.—The Body-centred Cubic Packing.
FIG. 144.—The Face-centred Cubic Packing.

the transformation which occurs at 900°, or the A_3-arrest, is reversed at 1400°, the A_4-arrest. S. Sato thus summarized the data derived from the X-radiograms, and plotted the results in Fig. 145 :

	Body-centred cube			Face-centred cube		
	20°	800°	1450°	1000°	1100°	1425°
α-edge . . .	2·86	2·89	2·93	3·65	3·66	3·68 A.

E. C. Bain, H. Shoji, and E. J. Janitzky studied the mechanism of the transformation from body-centred α-iron to face-centred γ-iron ; and for K. Honda and S. Sekito's observations on this subject, *vide* martensite, and the theories of hardening.

A. Westgren and G. Phragmen studied the X-radiogram of cementite and concluded that the crystals are rhombic, with the axial ratio $a : b : c = 0.891 : 1 : 1.329$. The dimensions of unit structure containing $4Fe_3C$ are $a = 4.518$ A., $b = 5.069$ A., and $c = 6.736$ A. The sp. gr. is 7·662 ; the vol. of unit cell is 154.3×10^{-24} c.c. ;

and the mol. vol.=23·43 c.c.   S. B. Hendricks has worked out the structure, which he says is of the co-ordination type with octahedra of iron atoms around central carbon atoms, as indicated in Fig. 146. The assumed structure explains the observed absence of the formation of solid soln. in the iron-carbon system between cementite and phases containing more or less carbon ; the hardness of cementite ; and the lack of metallographic characteristics that would require similarity of arrangement of iron atoms in some plane of cementite compared with a specific plane of α-iron.
FIG. 145.—The Lattice Constant of Iron at Different Temperatures.
FIG. 146.—Structure of the Cementite with Octahedra of Iron about Central Carbon Atoms.

The work on X-radiograms has shown that **solid solutions** are of two kinds : (i) Those in which the solute is a *substitution element, i.e.* one in which the atoms enter the space-lattice of the solvent and occupy the place previously occupied by the solvent atoms—for instance, nickel or silicon in solid soln. with iron.   This is illustrated by F. Wever's diagram, Fig. 147, where the black spots represent nickel atoms, and the others atoms of γ-iron.   (ii) Those in which the solute is an *interstitial element—die vagabundierenden Atomen—i.e.* one on which the atoms enter the space-lattice of the solvent and occupy open spaces between the solvent atoms—
FIG. 147.—Lattice of γ-Iron-Nickel Alloys—Substitution Element.
FIG. 148.—Lattice of γ-Iron-Carbon Alloys—Interstitial Element.

for example, carbon, nitrogen, and oxygen.   This is illustrated by F. Wever's diagram Fig. 148, where the black spots represent carbon atoms, the others atoms of γ-iron.   T. D. Yensen pointed out that the interstitial elements may enter the iron lattice in small amounts and so produce a condition which makes the lattice tend to change from the body-centred to the face-centred lattice when the solubility of the interstitial elements is greater.   All the interstitial elements have a low solubility.   Thus the solubility of carbon at 1475° in iron with the body-centred lattice corresponds with one carbon atom to every 125 unit cubes.   At that high temp.

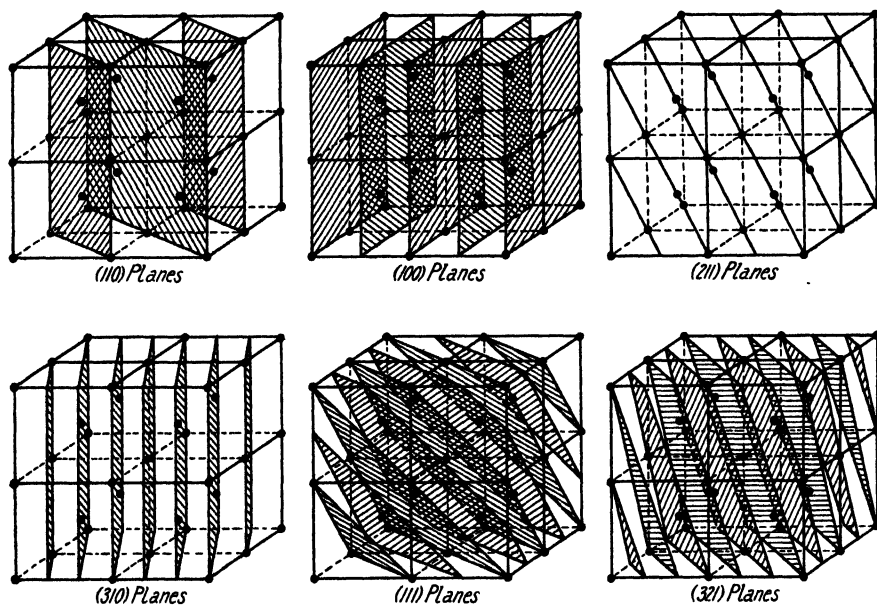
the thermal agitation of the atoms is very large, so that a carbon atom may travel from cube to cube with a high velocity. At low concentrations the carbon atoms may slip through the α- (body-centred) lattice without permanent distortion, but as the concentration is increased a point will be reached, depending on the temp., where the visits of the carbon atoms to the α-lattice are too frequent, and accommodation is provided by a change from the α-lattice to the γ-lattice. S. Sekito found that the variation in the lattice parameter is equivalent to 0·45 per cent. for every 1 per cent. of carbon—*vide supra*, martensite. A. Heinzel observed that elements of the 1st, 2nd, 7th, and 8th groups of the periodic system, if soluble in iron, and closely related to iron physically and chemically—*e.g.* manganese—generally widen the range of existence of the face-centred structure, which is normally from 906° to 1401°; whilst elements from the 3rd to the 6th group narrow the range of existence of γ-iron, and finally make it disappear—*e.g.* with vanadium exceeding 1·1 per cent. there is no γ-phase. These elements are not related to iron even if they are soluble in it. Carbon and nitrogen are exceptions. All elements of large


FIG. 149.—Systems of Atomic Planes.

atomic radius—*e.g.* the metals of the alkalies and alkaline earths, mercury, lead, thallium, bismuth, silver, and cadmium—are insoluble in iron. With still higher concentrations of carbon even the γ-lattice is insufficient, and the compound Fe_3C is formed. Interstitial atoms like oxygen and nitrogen may be too large to be able to pass freely from lattice to lattice as readily as does the carbon atom, so that it becomes permanently attached to the regularly spaced unit cubes. The stranger atom may displace the central iron atom, and this in turn displaces its neighbour, and so on until a number of the displaced atoms meet to form a face-centred cube. This action upsets the regularity of the whole lattice, the neighbouring central iron atoms are displaced, and as more stranger atoms enter, more and more γ- (face-centred) cubes are formed, until the entire α-lattice breaks down, and the γ-lattice is formed with stranger atoms in the centres at regular intervals. T. D. Yensen also inferred that if no stranger atoms (impurities) be present, there will be no change from the face-centred to the body-centred lattice, and that pure iron would not appear in forms other than that of $\alpha(\delta)$-iron. The subject was discussed by F. Bitter, and K. Heindlhofer.

Owing to the definite geometric arrangement of the crystal units, the atoms fall into a series of parallel planes inclined at different angles to the sides of the cube, and each system of planes includes every atom of the body-centred cube. These planes are illustrated diagrammatically in Fig. 149 by H. H. Lester and R. H. Aborn. A. W. Hull, and R. W. G. Wyckoff discussed this subject. Each set of planes may be regarded as a space-grating for the X-radiations ; for the equally-spaced reflecting planes are of such an order of spacing that interference phenomena in the reflections are possible. The grating constant, d, is the distance between the planes. An incident beam of X-rays passing through a mixture of small crystals may be arranged to give reflections from each of the possible systems of planes, and with a suitable arrangement — 1. 11, 8 — the
Fig. 150.—Portion X-ray Film for Stressed and Unstressed Iron (Diagrammatic).

spectral lines can be represented as the envelope of a series of circles with their centres in a straight line. Fig. 150, by H. H. Lester and R. H. Aborn, represents a portion of the two crystal spectra (i) for unstressed iron, and (ii) for iron subjected to a tensile stress. If the beam of X-rays is monochromatic, the lines are single.

M. Ettisch and co-workers found that in hard-drawn wires of metals with a body-centred cubic lattice only a single lattice plane, (110), lies in the section of the wire. The arrangement of the crystallites imparts a fibrous structure, so called because the arrangement was first observed in natural fibres like ramie and silk. E. C. Bain and Z. Jeffries observed that when a very coarse-grained metal with only a few grains is rolled it develops a complete assortment of orientations, indicating that a rotation of the crystal fragments occurs during deformation. The rotation of the microcrystals as a result of cold-working has been proved by the work of H. C. Burger, G. Tammann, F. Wever, C. Nusbaum, C. F. Elam, G. I. Taylor and C. F. Elam, A. Smekal, A. Ono, K. Becker and co-workers, F. Wever and co-workers, F. Körber, W. P. Davey and co-workers, R. Glocker, and G. Sachs and E. Schiebold. The resulting orientation depends on the nature of the metal and on the kind of cold-working. In iron, with its body-centred cubic lattice, the (110)-axis takes the axial direction of the bar, whilst with copper and aluminium, with their face-centred cubic lattices, the (111)-axis takes the axial direction of the bar along which the metals are stretched or drawn. According to G. Kurdjumoff and G. Sachs, the orientation of the crystals of rolled electrolytic iron, as revealed by the X-radiograms, and the stenographic projection of the polar sphere of the directions of reflection, for the (110)- and (200)-faces, show that S. T. Konobejewsky's single orientation is not satisfactory, but that three simultaneous orientations are required. The (100)-, (112)-, and (111)-faces are respectively parallel to the plane of rolling, and the (011)-, (110)-, and (112)-directions are parallel to the direction of rolling. The character of the polar figures for the (200)- and (110)-faces of iron recrystallized between 550° and 840° can also only be explained by a similar triple orientation. The orientations in the rolled and recrystallized iron are so related that two orientations in the recrystallized metal are obtained from those of the rolled metal by rotation through an angle of 15° in the plane of rolling, whilst the third orientation is the same in both cases. The relative intensities of various orientations are different in both cases. The structure of the metal recrystallized above the $a \rightarrow \gamma$-transition temp. is similar to that of recrystallized a-iron, showing that in the change from a- to γ-iron the two modifications take up a definite relative orientation. P. W. Bridgman studied the relation between the orientation of the crystal and Young's modulus (q.v.) for tungsten.

A. Ono found that the X-ray diffraction pattern of a-iron strained in extension, compression, and torsion shows that there are two kinds of symmetry in the strained

lattice. In the first kind the rotation of the lattice during strain takes place about one of the axes in a definite direction, and in the second kind the lattice rotates about an axis which may occupy any position in a definite plane. In α-iron strained in extension the symmetry is of the second kind, with the axis (110) more or less parallel to the direction of extension, whereas in the same metal strained by compression the symmetry may be of the first kind with the axis (111) in the direction of compression, or of the second kind with the axis of rotation (011) lying in the cross-sectional plane. In twisted α-iron the second kind of symmetry exists with the plane (110), and probably also the plane (211), in the horizontal position. The mechanism of the crystal arrangement of a strained metal is explained on the assumption that slip and rotation are the causes of distortion, and that the direction of slip is constant for each kind of lattice. The resistance to slip of a metal increases with a diminution in the grain-size, and this agrees with the fact that fine-grained metals are usually much harder and stronger than those in which the crystals are relatively large.

W. E. Williams studied the X-radiograms of hardened steel, and concluded that when a carbon steel is quenched from above the transformation point, all or part of the γ-iron is changed into α-iron, but the α-iron grains do not grow from independent centres. In the tempered state the radical pattern is not altered, and hence tempering does not produce a recrystallization of the distorted crystals. Consequently, the extreme hardness of martensite is not to be ascribed to this distortion. A. E. van Arkel and P. Koets observed that the number of crystals of γ-iron in mechanically deformed strips of steel is approximately proportional to the number of crystals of α-iron in the undeformed strips. S. Sekito found that the maximum distortion of the space-lattice is $\delta a/a = 0.004$ with cold-drawn wire reduced 0.2326 in diameter—cf. Fig. 151. If the modulus of elasticity is $E = 21 \times 10^3$ kgrms. per sq. mm., when the maximum internal stress $P = E \times \delta a/a$, or $P = 84$ kgrms. per sq. mm., this is a little less than the tensile strength, 88 kgrms. per sq. mm. for the cold-drawn wire. The values of $\delta a/a$ for 0.1, 0.3, and 0.5 per cent. carbon steels annealed at different temp. are shown in Fig. 151. Most of the internal stress is relieved by annealing at 400°. F. C. Elder, M. Ettisch and co-workers, S. T. Konobejewsky, M. Polanyi and K. Weissenberg, and G. Kurdjumoff and E. Kaminsky also studied the effect of cold-work, tempering, and composition on the lattice of carbon steels.

FIG. 151.—The Effect of Annealing on the Lattice Distortion of Steel by Cold-work.

When a metal passes from the liquid to the solid state, nuclei are first formed, and crystals begin to grow about the nuclei. In the case of iron, if the crystallizing forces had free play, the crystals would assume regular geometrical forms, cubes or octahedra. The crystals, however, grow more rapidly in favoured directions to form elongated crystals called **dendrites.** The dendrites are often described in terms of their imagined resemblance to some better-known object—e.g. fir-tree crystals. H. Capitaine prepared dendritic crystals with branches parallel to the cubic axes. Dendrites are sometimes found in the cavities or pipes of large ingots, hanging like stalactites from the roof. The dendrite of ferrite illustrated by Fig. 152 —a so-called pine-tree crystal—was found by D. K. Tschernoff formed in a cavity in an ingot of cast steel as the retreating liquid left the incompleted form. In 1775, P. C. Grignon described similar crystals formed in cavities in cast iron ; he said that under a magnifying glass the dendrites had " the appearance of a small metallic forest made up of trees with quaternary branches." E. F. Lange found pine-tree crystals encrusting a cavity in a pipe of a large steel casting. The crystals in some

cases were 14 to 15 inches long. They are kept in the museum of the Manchester Literary and Philosophical Society. E. F. Lange's analysis of drillings from the crystal gave : 0·43 per cent. of combined carbon; 0·191 Si ; 1·05 Mn ; 0·101 S ; and 0·098 P ; and an analysis of the steel outside the crystal area was : 0·345 per cent. combined carbon; 0·16 Si ; 1·02 Mn ; 0·08 S ; and 0·076 P. J. S. G. Primrose obtained a fir-tree crystal 19 inches long and 3 lbs. in weight from a pipe-cavity in a 50-ton steel ingot. F. C. G. Müller, and H. M. Howe poured the liquid metal out of the interior of partially frozen ingots at various stages of solidification, but invariably found the interior surfaces smooth and without any surface protrusion of crystal growths.

It is generally assumed that the primary axis forms first, and that the secondary axes are then quickly developed ; then follow the ternary axes and so on all in rapid succession. The branches thicken and elongate to form a branched structure or **crystal skeleton.** As H. Wedding puts it :

> In commercially pure iron the crystals show the form of an incomplete regular octahedron, that is to say, the external form corresponds to the octahedron ; the mass of the crystal, however, is not filled up, but is replaced by branches which run in a direction parallel to the axes of the octahedron, and consequently correspond to the position of the faces of the fundamental cube. Such branches have, as a rule, side branches standing at right angles to the main branches ; these also again often have perpendicular branches of the third degree, so that the whole is only the skeleton of an octahedron, and has an external form recalling that of the pine-tree.

FIG. 152.—Pine-tree Crystal of Ferrite (D. Tschernoff).

The formation of skeleton or dendritic crystals during the solidification of metals was described by F. G. Allison and M. M. Rock, A. W. and H. Brearley, H. G. Carter, C. H. Desch, J. A. Ewing and W. Rosenhain, A. L. Feild, J. D. Gat, F. P. Gilligan and J. J. Curran, A. Glazunoff, F. von Goeler and G. Sachs, W. H. Hatfield, C. T. Heycock and F. H. Neville, H. M. Howe and co-workers, T. Ishiwara, H. G. Keshian, V. N. Krivobok, N. M. H. Lightfoot, G. Masing, A. M. Portevin and V. Bernard, J. S. G. Primrose, W. Rosenhain, A. Sauveur, A. Sauveur and C. H. Chou, A. Sauveur and V. N. Krivobok, J. E. Stead, B. Stoughton and F. J. G. Duck, and R. Vogel.

P. C. Grignon said that when grey cast iron is in a perfect condition, it gives a very regular crystallization, every crystal being distinct and isolated. He described skeleton forms built up on the rectangular axes of the cubic system. The axes grow and thicken by the gradual deposition of particles of solid, until the interstices between the axes are filled up and the dendrite is formed. Its external shape is influenced by contact with neighbouring growths, and occasionally the boundary lines between the different growths can be detected. Solidified masses of iron or steel are composed of closely interlocked masses of dendrites—cf. Fig. 13, 1. 11, 4. The dendritic structure is revealed by suitably polishing and etching the surface— cf. Figs. 41 to 44. Fig. 153 (×4), by P. Oberhoffer, shows the unetched surface of steel with 0·4 per cent. of carbon, after fusion and solidification in vacuo. It shows the crystallization nuclei enclosed by cell-like boundaries—vide 1. 11, 4.

The dendrites are intermediary forms between crystal skeletons and fully developed crystals. The dendritic structure of iron or steel is sometimes called the *primary structure*, and the colonies of grains each enclosing the dendrites within its boundaries are called *primary grains*. If only one metal is under consideration, the dendrite will be chemically homogeneous ; but if the metal is associated with another element, the crystal axes which are the first to solidify contain more of the constituent with the highest m.p., and the portion last to solidify between the crystal axes will contain more of the constituent with the lowest m.p. The segregation of the molten alloy to form dendrites which are chemically homogeneous is called

dendritic segregation, or **intercrystalline segregation.** A. le Thomas, and L. Guillet discussed what they called the *heredity* of iron castings. The primary crystallization of binary, ternary, and more complex systems was discussed by F. Giolitti. The tendency of a metal to migrate from parts where it is highly concentrated to parts where it is less concentrated by the process of diffusion tends to make the metal homogeneous and to undo the state produced by dendritic segregation. This diffusion was discussed by F. Giolitti. It continues in the cooling metal after it has solidified, and it is promoted by slow solidification, by a prolonged heating of the solid at a high temp., and by slowly cooling the solid. J. E. Stead suggested that the presence of phosphorus, sulphur, and silicon in iron and steel favours dendritic segregation—*vide supra.* H. le Chatelier supposed that oxygen acts in a similar manner; and H. le Chatelier and J. Lemoine, manganese, silicon, nickel, and chromium. The subject was discussed by H. M. Howe, etc. A. Sauveur and V. N. Krivobok

Fig. 153.—Crystallization Nuclei in Cells of 0·4 per cent. Carbon Steel (P. Oberhoffer).

said that oxygen alone in pure iron or in iron with carbon or phosphorus or both does not produce persistent dendritic segregation; phosphorus can produce dendritic segregation in iron alone, as well as in iron-carbon alloys, and it causes the separation of carbon from steel with 0·17 per cent. carbon. Carbon and iron alone can produce dendritic segregation provided the solidification is fast enough. Crystallization was studied by A. Hultgren, C. H. Desch, A. W. and H. Brearley, N. T. Belaiew, C. A. Müller, P. Bardenheuer and C. A. Müller, and H. G. Keshian—*vide infra,* cast iron. A. Wingham discussed the internal strains set up in iron and steel during crystallization.

N. T. Belaiew showed that at least three types of crystallization occur in the production of steel. There are : (i) the *primary crystallization* which occurs in a liquid or mush and which furnishes dendrites ; (ii) the *granulation* which occurs in a completely solidified alloy and involves a rearrangement of the crystals to form grains of various sizes and dimensions; each grain has its own crystallographic orientation and is a distinct crystallographic unit. The result is to give a polyhedral structure to the solid soln. of austenite. (iii) The *secondary crystallization* takes place in the solidified and granulated metal and it results in the formation of the usual pearlitic structure. Consequently, the properties of the finished alloy are to be traced back to the dendrites of the primary crystallization and to their unavoidable heterogeneous composition; then to the granules—number, dimensions, cohesion, etc. ; and then to the secondary crystallization or pearlitic structure. F. Giolitti discussed the secondary crystallization of homogeneous and non-homogeneous austenite ; and the morphological relationships between the primary and secondary crystallization systems. N. T. Belaiew showed that the process of secondary crystallization or chemical decomposition starts at some point in each polyhedral grain, and ceases when it reaches the boundary of the grain. There is a neutral zone between two adjacent grains when the crystalline matter cannot assume the, orientation of either of the grains. As the cooling alloy approaches the eutectoidal temp., the excess ferrite or cementite will accumulate about the periphery

of the grains ; so that if the cooling proceeds slowly enough, the whole of the excess ferrite or cementite will form a membrane or shell more or less thick, leaving the while the interior forms eutectoidal pearlite.   On a plane section the resulting structure appears to have a **cellular** or **network structure**—*vide supra*, Figs. 137 and 138.   Hence the iron with 1·29 per cent. of carbon shows a network of white lines of excess cementite surrounding the grains of pearlite.   If the secondary crystallization proceeds rather rapidly by quick cooling, a certain amount of excess element will crystallize where it is formed, in the middle of the grain, and not at the boundary.   The lines of separation will follow the crystallographic planes of the crystalline grains.   The γ-iron, with its face-centred lattice, has four pairs of octahedral planes, and the separation of the excess ferrite or cementite will follow these planes.   On a secant plane such octahedral sections will then appear as **Widmanstätten figures,** which bear a distinct character in each grain.   The combination of the meshes with these figures can be called the **Widmanstätten structure.** Still a third type of structure—*the structure of large crystals*—might be anticipated where the conditions are such that granulation does not occur, and the deposit from the secondary crystallization arranges itself parallel to the dendritic axes. Such a structure usually occurs in isolated crystals ; thus N. T. Belaiew observed it in the D. K. Tschernoff's crystal, Fig. 152, which contained 0·60 per cent. of carbon. The subject was studied by N. T. Belaiew, F. Berwerth, O. W. Ellis, F. B. Foley, F. Giolitti, H. Hanemann, K. Harnecker, T. Kase, V. N. Krivobok, A. M. Portevin and V. Bernard, A. Sauveur, E. E. Thum, J. Young, and B. Zschokke.   T. Kase obtained the Widmanstätten structure in hypoeutectoid steels by annealing them above 1000° ; or by heating them until partly fused and cooling in air from above the Ar_3-arrest.   Hypereutectoid steels must be cooled from above the A_{cm}-arrest ; quenching them is not an effective process, and cooling slowly through the A_1-arrest destroys the characteristic structure.   The structure is produced in nickel steels by long annealing at the Ac_3-arrest, and then quenching in water, so that meteorites may have acquired the structure by a prolonged exposure to a very high temp. and subsequent rapid cooling.   For the observations of C. Benedicks, *vide* the iron-nickel alloys.   A. Sauveur and C. H. Chou observed that there is a close relation between the martensitic and the Widmanstätten structures.   A. M. Portevin showed that when the carbon is homogeneously distributed the cementite may separate between the grains (a) in the network of the junctures of the grains, or (b) it may become isolated in the interior of the grains themselves and its distribution there is governed more or less by the directive influence of the crystalline forces.   This includes intergranular distribution, Widmanstätten figures, and imprisoned cementite.   There may be also a pseudodendritic distribution arising from the irregular concentration of the solid soln., for the concentration is highest in the interaxial spaces of the dendrites formed during the primary crystallization.   The diffusion of the carbon may make the steel homogeneous.   To summarize :

	SECONDARY DEPOSITS		STRUCTURES
Secondary Structures {	At outlines of grains		Network
	In crystal structures {	parallel cleavage planes	Widmanstätten
		parallel to crystal axes	Large crystals

According to N. T. Belaiew, a steel with 1·80 per cent. of carbon furnishes the structure of large crystals ; one with 0·60 per cent. carbon, the network structure with large meshes ; and one with 0·55 per cent. gave the well-developed Widmanstätten structure shown in Fig. 154 (×6) and Fig. 155 (× 6).   The Widmanstätten figures were observed on a meteorite by A. de Widmanstätten in 1808, but no publication was made.   The figures attracted some attention, and they soon came to be known by their present name.   It was thought for a time that the figures were peculiar to meteorites, but they were found to develop on various metal alloys—*e.g.* the alloys of platinum and antimony by M. Chouriguine.   In 1900, F. Osmond observed on a steel ingot equilateral triangular markings which " recalled the Widmanstätten

figures which are known to belong to the regular octahedral system "; and J. O. Arnold and A. McWilliam also observed them on carbon steels. The subject was discussed by A. Sauveur, and A. Sauveur and C. H. Chou.

The fundamental conditions for the production of Widmanstätten's figures are that the alloy (i) crystallizes with the face-centred cubic lattice ; (ii) is subject to secondary crystallization ; (iii) is in the granulated state when secondary crystallization occurs ; and (iv) is cooled through the secondary crystallization so as to favour the deposition of the excess element, not at the boundaries only, but also inside the grains. The markings or lines on the surface of each grain are peculiar to itself. The interpretation of the lines requires a knowledge of the geometry of the regular octahedron. If such a solid be built of lamellæ lying parallel to the outer faces of the solid, there will be four sets of such lamellæ, since the regular octahedron has four pairs of parallel surfaces. Any sectional plane through the solid will show four sets of lines, each set of lines corresponding to the intersection of the cutting or secant plane and one of the sets of lamellæ, except when the secant plane lies parallel to any one of the faces of the solid, and therefore parallel to the corresponding set of lamellæ, in which case only three sets of lines will be produced. The majority of the grains show four distinct sets of lines. N. T. Belaiew studied
Figs. 154 and 155.—Widmanstätten Structure (N. T. Belaiew).

this subject in some detail. H. Wilkinson, A. M. Portevin, F. Giolitti, and S. V. Bielyansky discussed the morphology of proeutectoidal or excess cementite— vide supra.

According to T. Kase, a hypoeutectoid steel gives the Widmanstätten structure on annealing above 1000° or on heating it to partial melting and cooling in air from a temp. above the Ar_3-point. Hypereutectoid steel must be cooled from above the Acm-point. Quenching is not an effective method and cooling slowly through the A_1-transformation point destroys the characteristic structure. The Widmanstätten structure is obtained in iron-nickel alloys by a long annealing above the Ac_3-point and then quenching in water, and the formation of this structure in meteorites may be due to a long exposure to a very high temp. and subsequent rapid cooling.

The **corrosion figures** of iron are cubical, although J. A. Ewing and W. Rosenhain [2] did not find it easy to obtain a good development of the geometrically etched figures. The polygonal boundaries of the grains divide a polished and etched surface into a number of areas—Fig. 137 ; each area represents a section of a crystal grain. Each grain is built up of a large number of what T. Andrews called secondary crystals, which have different orientations in different grains. This was shown by J. E. Stead in the case of a steel with 4·5 per cent. of silicon. A fractured ingot exhibits large crystals ; and by deeply etching a polished surface he obtained

a fine development of regularly oriented elements of which the crystal grains are built up—Fig. 14, 1. 11, 4. As F. Osmond and W. C. Roberts-Austen express it, the general orientation of these secondary crystals remains constant in the area of each grain. Each grain has grown from a nucleus; each grain is built up of similarly oriented parts, but the orientation changes from grain to grain. According to E. Heyn, and J. E. Stead, the corrosion figures of α-iron occurring on the (001)-face are squares parallel to the edges of the cube face. They were also observed by F. Osmond and G. Cartaud. Some of the corrosion figures or etched pits may appear like triangular wedges when the section cuts the crystal grain at certain angles. H. H. Potter and W. Sucksmith showed that the etch-planes of iron in a 10 per cent. alcoholic soln. of nitric acid are (100). C. A. Edwards and L. B. Pfeil observed that square etching pits are sometimes obtained with a diagonal of a large crystal in the direction of straining. C. F. Elam showed that when the cube face lies in the plane of the specimen, cubic etching pits are obtained in that and in no other position. J. E. Stead also observed that the different faces are attacked at different rates by dil. nitric acid. If a cube face of iron be pricked by a needle and then strongly etched by the acid, the hole, originally round, becomes square, because the sides of the hole are dissolved away at different rates. The sides of the square become parallel to the cube face. Possibly the ratio of the rate of solution of the (001)-face to that of the (011)-face is equal to the ratio of the length of one of the square sides of a right-angled triangle to the length of the hypotenuse, or about $1 : \sqrt{2}$. Sections of the same crystal of iron cut parallel to and at an angle to the cube face, when immersed in acid and connected by wires to a galvanometer, give an electric current, proving that the cube face is electro-negative to the other face. F. Osmond and G. Cartaud observed that the corrosion figures on the alleged β-iron are similar to those on α-iron; and with γ-iron the lines of corrosion on the (001)-face are neither so continuous nor so soft as those on α-iron. Etching figures were obtained on manganese steel with a soln. of ammonium copper chloride, or by 10 per cent. nitric acid; and on nickel-chromium steel, by a dil. hydrochloric acid soln. of ferric chloride. The etching is irregular, and even after deformation followed by annealing at 1300° shows the primary crystals very clearly. G. Tammann and co-workers, P. Oberhoffer and A. Heger, J. Czochralsky, V. N. Svechnikoff, J. C. W. Humfrey, and K. Harnecker and E. Rassow studied the corrosion figures of iron. H. S. George said that the etching figures on ferrite generally assumed to be pits are really pyramids standing in bas-relief.

F. Osmond and G. Cartaud observed that when a crystal of iron with a polished cube face is introduced in a bath of molten boric acid at 800°, needles of boric acid congealed at first on the polished face and preserved it provisionally from attack. Instead of the crystals arranging themselves in their natural order, they follow the direction of the system of iron crystals to form **synchronous crystallisation figures.** F. Osmond and G. Cartaud also found that in a sample of crude manganese steel, little, hard nuclei have segregated to form **segregation figures.** The principal planes of segregation of γ-iron are the (111)-planes; but secondary planes, (001), (011), (012), and (122), may exist. G. Rose, and G. Tschermak also observed that the rhabdite, $(Fe,Ni)_3P$, of some cubic meteoric irons is oriented in accord with the three cube faces; and G. F. Kunz and E. Weinschenk noted that in one case the rhabdite is arranged parallel to the Neumann's bands.

According to H. O'Neil,[3] the cubical **cleavage** is perfect, and, according to O. W. Huntington, meteoric iron shows in addition octahedral and dodecahedral cleavages. This subject was discussed by A. Breithaupt, J. Cornuel, and H. von Dechen. F. Sauerwald and co-workers found that at low temp. cleavage takes place along the cubic planes of single crystals of iron. E. Sütter obtained **overgrowths** on tungsten. According to A. Sadebeck, there are **gliding planes** about the (211)-face—*vide infra,* slip-bands, discussed by O. Mügge, G. Tammann and A. Müller, W. Schwinning and E. Strobel, H. O'Neil, S. T. Konobejewsky, F. Wever, and J. A. Ewing and W. Rosenhain. H. Gough found that α-iron has three crystallo-

graphically different slip-planes, namely, (110), (112), and (123), whilst other metals usually have one kind of slip-plane. The **pressure figures**—*vide infra*, Neumann's bands—were discussed by G. Tammann and A. Müller, who found that if an indentation be made in a crystallite of a polished surface by means of a gramophone needle, the slip-lines are regularly oriented around the impression if there are no inclusions in the crystallites; but in the presence of such impurities the slip-lines are curved around the inclusion. Stress figures were studied by W. Köster, and H. Jungbluth. F. Osmond and G. Cartaud reported the following results:

	a-iron	β-iron	γ-iron
Planes of translation parallel to (111)	Difficult	Unknown	Easy
Folds	Dominant	Exclusive	Absent
Mechanical ∫twinning planes	(111)	Unknown	(111)
twinning ⎩planes of junction	(112)	Unknown	(111)
Annealing ∫twinning planes	Unknown	Unknown	(111)
twinning ⎩planes of junction	Unknown	Unknown	(111)
Face of maximum hardness	(111)	—	(011)
Planes of easiest etching	(001)	(001)	(001)

Both terrestrial and meteoric iron occur in solid masses which in some cases consist of one crystal individual and in other cases of several individuals. Some specimens have a scaly structure. **Twinning** occurs about the (111)-plane; and in some cases there are lamellar intergrowths about the (211)-plane. This subject was discussed by A. Sadebeck, C. H. Mathewson and G. H. Edmunds, C. H. Mathewson, K. Harnecker and E. Rassow, L. W. McKeehan, G. I. Taylor and C. F. Elam, H. O'Neil, W. E. Hughes, O. Mügge, S. Tamura, V. N. Svetchnikoff, and G. E. Linck. Twinning produced during the solidification of the molten alloy is called **congenital twinning** by F. Osmond and G. Cartaud. In the plastic deformation of metals certain crystal units may form *macles* or twin crystals instead of slipping, owing to the crystal units rotating into a new position symmetrical with their initial orientation. J. A. Ewing said that the nature of twinning is perhaps most easily intelligible if the crystals are considered to be built up of layers of brickbats, and after one layer has been completed the next layer has all the bricks turned round through an angle of 180°. The result would be a twin formation. According to H. M. Howe, a twin or macle can be recognized in a polished section of a metal (i) by the presence of re-entering angles; (ii) as a parallel-sided area within a given grain. It differs from the metal on both sides of it in the directions of the slip-bands, which zigzag on entering and leaving it. A twin can also be recognized (iii) in strength of the contrast between the treads and rises of the slip-bands; (iv) in the tint to which it etches; and (v) in the shape of its corrosion figures. Broad annealing twins are common in γ-iron and austenite, but they are rare in a-iron or ferrite. **Annealing twinning** does not occur on deformation but on annealing after deformation. Presumably the plastic deformation produces a stress in certain rows of crystal units which is not sufficient to cause them to rotate into the twinned position until the high temp. of annealing has made the metal mobile enough to allow the particles to move in obedience to the stress. Secondary or postgenital twinning is usually multiple or polysynthetic; and it may be formed mechanically by the deformation, or it may be produced by annealing at a suitable temp. after deformation. According to W. Rosenhain and D. Ewen, the slight deformation produced by the saw used in cutting a section for microscopic examination, by blow-holes, or by polishing, may be sufficient to produce twinning when the metal is subsequently annealed. C. A. Edwards and H. C. H. Carpenter found that twinning occurs in a marked degree when steels are quenched, and they assume that martensite is twinned austenite—*vide supra*; and C. A. Edwards discussed the formation of twinned crystals by direct mechanical strain. W. Rosenhain doubted the twinning of steel during quenching. According to J. E. Stead, the twinning observed in steel hardened by quenching from 1000° is always of the prismatic type, and the martensite of which the twins consist is oriented differently from the martensite grains in which they are embedded. H. C. H. Carpenter and

S. Tamura observed that annealing twins in metals are structures which are in a relatively stable state. C. A. Edwards and H. C. H. Carpenter assume that the twinning of crystals, which occurs when a steel is quenched, is attended by the production of amorphous metal. W. Rosenhain, J. E. Stead, and H. M. Howe did not accept this hypothesis. Most cases of artificial twinning are produced by annealing after deformation. Annealing twins are so rare in α-iron or ferrite that the few cases reported are suspected by some to be mechanical twins. H. M. Howe, E. Heyn, A. Baykoff, and O. Mügge said that α-iron may form twins ; and W. Rosenhain observed twinning with a steel with 1·94 per cent. of carbon and traces of manganese. F. C. Thompson and W. E. W. Millington attempted to produce annealing twins in ferrite without satisfactory results ; but V. N. Krivobok annealed electrolytic iron at 593° for 30 mins. and obtained a structure having the appearance of twinning, but which was shown to be a result of progressive crystallization along the deformation lamellæ. When annealed after being strained, unlike α-iron or ferrite, γ-iron and austenite readily form twins. This behaviour is probably connected with the arrangement of the atoms in the space-lattice. In general, twinning occurs readily with metals having the face-centred lattice—e.g. α-iron, and austenite—but twinning seldom, if ever, occurs with metals having the body-centred cubic lattice—e.g. ferrite or α-iron. S. Tamura observed what appeared to be a twin in specimens of wrought iron and mild steel ; only one twin-like crystal appeared within an individual crystal of ferrite, and the twin never exceeded 0·08 mm. in length. Hence it was doubted if the structures were true annealing twins, and he called them *pseudo-twins*. W. Rosenhain also observed a case where what appeared to be a twin was not really so, because slip-bands cross it without deflection. H. O'Neil, and G. I. Taylor and C. F. Elam discussed the distortion of iron crystals.

In 1848, J. G. Neumann observed that a sample of meteoric iron from Braunau, described by C. C. Beinert, showed in addition to the cubic cleavage planes other lines in the direction of the triakisoctahedral or (221)-face. The fine etching lines or bands were supposed to be produced by thin flakes in twin-formation, which were less attacked than the main mass. M. A. F. Prestel also observed these bands in artificial iron ; and they were called by A. Brezina **Neumann's bands,** or *Neumann's lines,* or *Neumann's lamellæ,* or *Neumann's figures.* They are narrow straight bands running in definite directions. They appear black under vertical illumination, and white when illuminated obliquely. They represent thin, mechanically twinned lamellæ or strata which are produced in iron, and some other metals, by deformation, and most readily by shock, impact, or explosion. If the suddenly applied dynamic stress has caused the rupture of the metal, the bands will generally be found near the seat of the fracture. M. Matweieff said that in polishing with emery, twinning occurs when the direction of rubbing coincides with a cleavage plane ; but A. M. Portevin and J. Durand consider that the lines so produced are not Neumann's lines, but they originate from the scratches of the polishing powder producing interstrain in the layers beneath, and this interstrain is relieved by the etching. Deep etching makes them disappear. F. Osmond and G. Cartaud found that when a crystal of iron is cleaved, Neumann's bands appear in abundance on both sides of this cleavage face. The bands are more easily produced by shock at low temp. ; they are readily obtained by shock at ordinary temp., but they are not formed at a blue temper heat or a higher temp. ; and R. A. Hadfield found that they appear when iron is ruptured by tension at the temp. of liquid air. F. Robin was unable to produce them by moderate shock in wrought iron or very ductile steels except at −185°, yet he found them in 0·07 per cent. carbon steels which had been struck by a projectile moving at the rate of 380 metres per sec. In very brittle steels with 1 per cent. of phosphorus he produced the bands by shock at 20° up to 600°, but not at 700°. F. B. Foley obtained Neumann's bands as ridges and furrows when mild steel discs are subjected to the impulse from the action of explosives. T. E. Stanton and L. Bairstow found that the bands were developed by breaking ductile Swedish

iron by a single severe blow or by a small number of moderate blows, but not by a large number of light blows. The Neumann bands are more or less parallel and follow the orientation of the grains, so that the lines on a cleavage face are parallel either to the diagonals of the square or to the lines which join the angles as the centres of the opposite edges. The appearance of Neumann's bands in a sample of wrought iron is given in Fig. 156 ($\times$150) from a photograph by H. C. H. Carpenter. Fig. 157 ($\times$250) represents Neumann's lamellæ with indentations assumed by F. Osmond and G. Cartaud to be connected with the formation of another system of lamellæ. The specimen was etched with picric acid. The bands are sometimes visible to the naked eye. After polishing to low relief they may appear as slight depressions on the faces of the cube, or they may be in relief. A. M. Portevin and J. Durand do not agree with M. Matweieff that the Neumann bands stand out in relief. Alcoholic picric acid or dil. nitric acid (1 : 500) are convenient reagents. The lamellæ may have a uniform thickness, or they may be more or less indented. The subject was also discussed by F. B. Foley and co-workers, P. von Jeremejeff, H. von Jüptner, G. E. Linck, L. W. McKeehan, O. Mügge, H. O'Neil, F. Osmond and G. Cartaud, J. Seigle, G. Tammann and H. H. Meyer, etc.

According to M. Matweieff, Neumann's bands are always parallel to the Widman-

FIG. 156.—Neumann's Bands   FIG. 157.—Indented Neumann's Bands
(H. C. H. Carpenter).   (F. Osmond and G. Cartaud).

stätten figures, but H. M. Howe said that they are only so in the majority of cases. F. Robin found that the Neumann bands develop normally to the direction of impact of a projectile, but H. M. Howe observed that in silicon steel, when formed by blows, the bands run preferentially 45° with the direction of impact. The contacts between Neumann's bands and the enclosing metal are assumed to be planes of low cohesion, because F. Osmond and co-workers showed that fracture follows Neumann's bands. J. E. Stead, and C. H. Desch showed that there is no evidence that Neumann's bands do not affect the hardness of the metal. According to F. Berwerth and G. Tammann, Neumann's bands are obliterated on rapidly heating meteoric iron to 800°, and with a slower rise of temp. they disappear at a lower temp. H. M. Howe said that they do not disappear at 800°, but they do so at 950°. This means that at the A_3-arrest, when α-iron passes into γ-iron or austenite, the bands are affected, and that in the presence of nickel the transformation temp. is lowered from 900° to 800°. According to F. Osmond and co-workers, the formation of a Neumann's band at an angle to one already formed may produce a displacement analogous to a fault.

The Neumann bands are oriented differently from the crystal, and are considered to be a fine form of twinning. Both J. G. Neumann, and G. Tschermak consider that

the Neumann bands are produced by a fluorspar twinning, where the octahedral face is the plane of twinning, and the ternary axis, the axis of twinning. There are four ternary axes ; and the 24 faces of the four sub-elements, identified with the planes of Neumann, are consequently parallel to the triakisoctahedra or (122)-faces. G. Rose could not decide whether the bands are parallel to the (122)- or (112)-faces. A. Sadebeck observed on the cleavage face of a dominant cube that the faces terminal to those of the bands, which make an angle of 45° with the sides of the square, make an angle of $144\frac{3}{4}°$ with the plane of the face of the cube. Supposing that these terminal faces are the cleavages of the sub-elements, he concluded that the plan of twinning was triakisoctahedral—the axis of twinning is then perpendicular to a face of the triakisoctahedron. Hence, in the case of the two elements twinned in accord with the law of association, when two faces of the twinned cubes cut one another in the direction of a common diagonal, the faces of one of these cubes is the face of the trapezohedron (112) of the other, and at the same time the octahedral face of the dominant cube is the rhombododecahedral face of the secondary cube. Like J. G. Neumann, and G. Tschermak, G. E. Linck assumed that the law of fluorspar twinning applies, but he considered that the junction faces should be (112) and not (122). The planes of junction then have the same rotation for the two unit elements twinned ; and (112)-planes are at the same time the planes of translation. He thus showed that Neumann's lines are due to lamellar twinning with gliding on the planes of the icositetrahedron (211). F. Osmond and G. Cartaud found that G. E. Linck's theory best fitted their observations on the bands parallel to the (112)-planes. S. W. J. Smith and co-workers showed that Neumann's bands are due to lamellar twinning, and that they are of secondary origin due to strain ; lamellar twinning by shearing is possible on the (211)-planes of a body-centred cubic lattice—e.g. kamacite, α-iron taenite, and γ-iron have a face-centred cubic lattice. H. C. H. Carpenter and S. Tamura have suggested that Neumann's bands of the kamacite or meteoric irons were produced by the shock of impact when the meteorite struck the earth's surface. C. H. Mathewson and G. H. Edmunds showed that X-radiograms indicate that the inner structure of the bands is that required to produce the observed twinning of the body-centred cubic lattice. The mechanism of the formation of Neumann's bands was discussed by W. E. W. Millington and F. C. Thompson. G. Tschermak thought that the bands are congenital twinned crystals, but F. Osmond and G. Cartaud said that if so, the twins should have the same magnitude as the crystals from which they are derived, since the development of the two twinned elements has been simultaneous ; on the contrary, the Neumann twins are extremely small, and they are frequently inflected and thrust aside by meeting lamellæ of another system. It is therefore inferred that the Neumann bands are mechanical twins in α-iron. This is in agreement with H. le Chatelier, A. M. Portevin and J. Durand, T. B. Focke, O. A. Derby, G. T. Prior, L. J. Spencer, F. Osmond and co-workers, etc. W. Rosenhain and J. McMinn added that the bands are sections through lamellæ or plates, and not thin rods ; they believe that they are not the nature of mechanical twins, but result from localized deformation brought about by the rapid application of a heavy stress. After slowly straining a sample of iron, and causing numerous slip-bands to appear, the subsequent abrupt application of a stress fails to produce Neumann's bands, but the additional deformation under impact takes place by a further slip of some of the slip-bands previously developed by the slow plastic strain.

F. Osmond and G. Cartaud continue : there are no known twins in β-iron due to mechanical twinning ; and with γ-iron a slight deformation produces effaceable lines of translation, but more severe deformation produces mechanical twins. The twinning which occurs when γ-iron in cast nickel-chromium steel is deformed cold and then annealed at 1300° is the same as the mechanical twinning with (111) as the plane of twinning and the plane of junction. The transformation of γ-iron into α-iron starts below 400° in the case of sudden quenching and causes considerable stresses. These stresses involve a more or less complete formation of an infinity

of twins parallel in each grain to the four pairs of octahedral faces, hence the frequency of squares and equilateral triangular figures on a chance section. Hence the structure of martensite is peculiar to γ-iron, even though the iron is not for the most part present in the γ-state. Even after tempering, when all the iron has resumed the α-state, if the temp. and duration have been sufficiently controlled to prevent the reconstitution of equiaxial grains which characterize α-iron, the pseudomorphous α-iron may be retained on the martensite structure of γ-iron. The grains are in this way cut up by an infinite number of extremely thin lamellæ parallel to four different planes. The continuity of the (001)-cleavages is broken, and the natural fragility of α-iron due to these cleavages is evaded. Hence the parts played by quenching and tempering in the manufacture of different varieties of mild steels. The structure of martensite is that of the octahedral meteoric irons on a reduced scale. These irons are formed of comparatively thick lamellæ parallel to the four pairs of regular octahedral faces. The structure of γ-iron is preserved by the iron in the α-state, because in the presence of nickel the A_3-transformation is lowered to such an extent that the α-iron cannot resume its natural structure of equiaxial grains. The position is that of martensite tempered at a moderate temp. The α-iron remains crystallized on the axes of the γ-iron. G. E. Linck said that the

FIG. 160.—Slip-bands (J. A. Ewing and J. C. W. Humfrey).

octahedral meteoric irons are polysynthetic aggregates of four twinned cubic sub-elements with a dominant cube following the ordinary law : (111)-plane of twinning and plane of junction. F. Osmond and G. Cartaud found this in agreement with their observations on pressure figures ; and in accord with G. E. Linck's theory, a (001)-face of the dominant cube cuts the associated four twinned secondary cubes on the (122)-planes ; and every pressure-figure on such a face of the dominant cube is characteristic either of a (001)-plane or of four (122)-planes variously oriented. No other figure is formed.

The deformation of some metals produces lines on the polished faces of some crystals. In 1895, O. Mügge [4] showed that with ice, cyanite, etc., the lines are due to a translation and not twinning, and, in 1899, he made a similar observation with respect to metals. He called the markings *translation-banding—Translationsstreifung*. The subject was discussed by E. Heyn in 1900. Independently, about the same time, J. A. Ewing and W. Rosenhain described a similar phenomenon, and they called the translation bands **slip-bands**. F. Osmond and G. Cartaud called them *lines of translation*, and F. Robin, *lignes de glissement*. According to J. A. Ewing and W. Rosenhain, if a metal be strained past its yielding-point, the elastic limit, the faces of the crystals show fine black lines (Fig. 158), which increase

in number as the strain increases (Fig. 159). The lines first appear on certain crystals nearly transverse to the pull; but as the strain increases, lines appear on other grains. Intersecting lines then make their appearance. Such a strained surface is illustrated by Fig. 159. As J. Muir has shown, a piece of iron strained beyond its elastic limit will recover its original elasticity if it be allowed to rest for some time or if it be heated to 100°. The dark lines do not disappear, but they do disappear if the surface be lightly polished in the usual manner. If, however, the deformation has been severe, as, for instance, in the vicinity of a fracture, when the surface is repolished and simply etched traces of the old slip-bands may reappear. Ordinary slip-bands produced by a moderate deformation are unlike bands produced by twinning and Neumann's bands, in that they disappear when the surface is repolished. The slip-bands are not actual cracks in the surface, but rather slips along cleavage planes or gliding planes of the crystals. These slips produce steps, so to speak, on the polished surface. W. Rosenhain observed that the smallest displacement is not more than 0·00002 in., or of the order of wave-length of light, and when the deformation has not been severe, a displacement of 0·0001 in. is observed. Other things being equal the greater the number of steps, the smaller their depth ; and with progressive deformation a given step breaks up into a number of steplets. The angle of the steps changes on passing from grain to grain. The uplift of the grains was demonstrated by W. Rosenhain, W. Rosenhain and J. C. W. Humfrey, G. I. Taylor and C. F. Elam, H. O'Neil, H. F. Moore and T. Ver, H. M. Howe and A. G. Levy, C. Frémont, P. Gaby-Aché, and F. Osmond and co-workers. The bands may appear in almost parallel lines, or the lines may deviate independently. J. C. W. Humfrey observed that with tension the first slip-bands are confined almost entirely to the central parts of the crystals, and spread only gradually towards the boundaries as the straining becomes severe; whereas H. M. Howe found that with a compression the slip-bands start more frequently at or near a grain boundary. Those which propagate from one grain into a neighbouring one enter the new grain via the grain boundary. When the slip-bands pass through a zone of twinned crystals, they may be obliterated, or they may continue with a change of direction into the twin and so form a series of zigzag lines. The zigzagging of the slip-bands has been used to demonstrate the presence of twinned crystals. J. A. Ewing and W. Rosenhain, and F. Osmond and G. Cartaud agree that the slip-bands in ferrite follow octahedral directions; and the former workers also observed them to follow cubic directions. H. C. H. Carpenter and C. A. Edwards showed that the twinning of the crystals of some metals can be produced by direct mechanical deformation; and C. A. Edwards inferred that since mechanical deformation is not always accompanied by slipping alone, but may produce fine twinned lamellæ, it may be that what are now regarded as slip-bands are really extremely fine twinned lamellæ far beyond the resolving power of the ordinary microscope. According to J. E. Stead, the tensile strain in iron is the sum of two factors—internal and external slips. F. C. Thompson and W. E. W. Millington inferred that in a single crystal of iron, or in a coarse aggregate, the dodecahedron (110) is the first plane of movement under stress, and in this case the elastic limit is low. In normal iron or mild steel the elastic limit is reached when the cube or (100)-face movement is initiated. Under higher stresses some movement on the dodecahedral face accompanies the deformation on the cube face.

The production of slip-bands by repeated stresses was discussed by W. E. W. Millington and F. C. Thompson, J. A. Ewing and J. C. W. Humfrey, F. Rogers, W. Rosenhain, and T. E. Stanton and L. Bairstow. The former workers subjected Swedish iron with a breaking stress of 23·6 tons per sq. in. to a series of alternating stresses, 9 tons per sq. in., repeated 400 times per min. On examination it was found that fine slip-bands appeared in a few crystals after a few—say 5,000 per min.—reversals of stress, as shown in Figs. 158 to 160. With a greater number of reversals—say 40,000 per min.—the slip-bands increase in number, and those which first appeared broaden and develop into small cracks, as shown in Fig. 161.

If the specimen be repolished, so as to clear off the slip-bands, the cracks alone become visible, as at A, Fig. 161. The crack or flaw gradually creeps right across the specimen when the number of alternations is still further increased, as shown in Fig. 162. Finally the specimen breaks. Quoting J. A. Ewing and J. C. W. Humfrey's own words :

Whatever the selective action of the stress is due to, the experiments demonstrate that in repeated reversals of stress certain crystals are attacked, and yield by slipping, as in other cases of non-elastic strain. Then, as the reversals proceed, the surfaces upon which the slipping has occurred continue to be surfaces of weakness. The parts of the crystal lying on the two sides of each such surface continue to slide back and forth over one another. The effect of this repeated sliding or grinding is seen at the polished surface of the specimen by the production of a burr or rough and jagged irregular edge, bioadening the slip-band, and suggesting the accumulation of débris. Within the crystal this repeated grinding tends to destroy the cohesion of the metal across the surface of the slip, and in certain cases this develops into a crack. Once the crack is formed, it quickly grows in a well-known manner, by tearing at the edges, in consequence of the concentration of stress which results from lack of continuity. The experiments throw light on the known fact that fracture, by repeated reversals or alternations of stress, resembles, in its abruptness, fracture resulting from creeping flaw, in the absence of local drawing-out, or other deformation of shape.
FIGS. 161 and 162.—The Passage of Slip-bands into Cracks. Polished Suifaces with Small Cracks and with a Large Crack respectively.

J. C. W. Humfrey [5] observed that the surface of the crystals of electrodeposited iron, after etching, showed peculiar wavy markings and numerous cavities filled with electrolyte. W. E. Hughes found that the lines of a fibrous deposit on a cylindrical cathode appear as wavy annular rings, but if the deposit is not of the fibrous type, the lines have no regular relation in passing from grain to grain, but on individual grains the herring-bone structure may appear. Increasing the depth of etching broadens the lines, and with high magnifications and deep etching the staircase structure may appear. The lines are common to deposits from chloride and sulphate soln.; they are formed with high and low current densities; the formation of the lines is not much affected by temp.; the lines are found in deposits of various thicknesses—0·005 to 0·015 in.; and the lines do not appear in deposits containing a large proportion of foreign matter—e.g. oxide, or, according to W. A. Macfadyen, carbon. J. A. Ewing and W. Rosenhain proved that slip-bands have been shown to be the result of a stress—mediately or immediately; and E. J. Mills showed that when metals are deposited electrolytically, a press. is produced owing to the contraction of the deposit. He called the pressure electrostriction. Observations on electrostriction were made by E. Bouty, G. C. Stoney, H. Stäger, V. Kohlschütter and E. Vuilleumier, O. Faust, and F. Credner. E. J. Mills considered that the press. of electrostriction may amount to 109 atm., and E. Bouty,

to 350 atm. According to W. E. Hughes, the lines in electrodeposited iron are slip-bands produced by electrostriction.

The path of the plastic deformation of a metal is internal, and when rupture occurs, the fracture is itself a path of deformation. When rupture does not occur, the internal path of deformation may show itself as a disturbance on the outer surface. With a slaty substance the path of deformation follows the parallel planes of lamination ; in a jointed substance, like brickwork, the path is along the joints ; in a fibrous substance, like wrought iron or wood it follows the fibre ; and in a crystalline substance, like mica or unburnt steel, it follows the crystal planes. Geometrical lines or lines of preferential deformation—**lines of flow**—produced by moderate deformations and occurring on polished surfaces were described by W. Lüders [6] in 1860, and by L. Hartmann in 1896. They are hence called **Lüders' lines** or *Hartmann's lines*. According to P. Breuil, in the bending of a plain bar
FIG. 163.—Lüders' or Hartmann's Lines produced in the Deformation of a Plain Iron Bar.

(Fig. 163) two systems of lines start under the knife-edge on opposite sides of the bar. The lines cut one another at the same angle ; the two groups of lines are symmetrical ; and they do not unite at first, but spread rapidly from one part to another of the bent surface, leaving a central space as a kind of neutral zone without lines. The lines then disappear, the neutral zone is deformed, and finally rupture occurs. L. Hartmann and A. Nadai showed that the lines form families of isogonal cycloids. E. Heyn said that Lüders' lines appear earlier than slip-bands when polished test-pieces are subjected to a tensile stress. The production of these lines was also discussed by P. Breuil, C. H. Carus-Wilson, C. Chappell, C. Frémont, G. H. Gulliver, E. Heyn, H. M. Howe, J. E. Howers, J. B. Johnson, W. Mason, M. Matweieff, P. Oberhoffer and M. Toussaint, F. Osmond and co-workers, A. M. Portevin and J. Durand, H. S. Rawdon, F. Robin, J. Seigle, and S. W. J. Smith and co-workers. B. C. Laws and A. O. Allen studied the lines of maximum stresses in steel plates. C. Chappell suggested a connection between Lüders' lines and brittleness ; H. Fowler studied the hardness in the vicinity of Lüders' lines.

It has just been shown that the plastic strain or deformation of metals is not a homogeneous shear such as is the case with a viscous liquid, but is rather the resultant effect of a limited number of separate slips. When a stress is great enough to cause a crystalline plate to rupture, the resistance to shearing offered by the cohesion of the crystalline particles is not greater before than after the slip has taken place. Indeed, the cohesion between the particles seems to increase progressively as the slip or deformation increases in magnitude. Once slip has occurred the deformation does not continue when the deforming stress is again applied ; a greater stress is needed to produce further deformation. The cohesion of the deformed metal increases during the test. The explanation of the phenomenon offered by G. T. Beilby [7] involves the assumption that iron, and other metals can exist in an amorphous state—**amorphous iron.** The term "amorphous" is contrasted with the term " crystalline " ; and it is intended to connote a state in which the orientation or regular, orderly arrangement of the constituent parts characteristic of the crystalline state is absent. An ordinary liquid is in the amorphous state. When a liquid is cooled without undergoing any critical change or crystallization, it forms an undercooled liquid, and when the viscosity is great enough, an amorphous solid. Ordinary glass is an example of a congealed liquid or an amorphous solid— *vide* 1. 9, 6. G. T. Beilby said :

In the operation of polishing, a true skin is formed over the polished surface. This skin gives unmistakable signs that it has passed through a state in which it must have possessed the perfect mobility of a liquid. In its final state it possesses distinctive qualities which differentiate its substance very clearly from that of the unaltered substance beneath. It

is, for instance, much harder, and, even when formed on the surface of a crystal on which the hardness varies in different directions, its hardness is the same in all directions. The discovery that layers of a solid many hundreds of molecules in thickness can have the mobility of the liquid state conferred upon them by purely mechanical movement opens up a new field of inquiry into the internal structure of metals which have been hardened by cold-working. A theory of hard and soft states is suggested in which hardening results from the formation at all the surfaces of slip or shear of mobile layers similar to those produced on the outer surface of polishing. These layers retain their mobility for a very brief period, and then solidify in a vitreous amorphous state, thus forming a cementing material at all surfaces of slip or shear throughout the mass. The term " vitreous " here employed narrows the field to amorphous substances which in some degree resemble the glass-like form assumed by the silicates when they are solidified from the molten state. . . . The transient existence of the mobile phase makes slip and movement among the lamellæ possible and easy, and it is the sudden resolidification of these mobile layers into a non-crystalline, vitreous condition which arrests deformation under a given deforming stress. The original surfaces of any slip are now cemented together by the more rigid material, and new surfaces of slip are developed only by higher stresses. The plasticity of the crystalline state is thus gradually used up, and the aggregate as a whole becomes more and more rigid. When this has reached a certain stage, further increase of stress leads, not to plasticity flow, but to disruption.

The general effect of mechanical cold-work is to lower the electrical conductivity (A. Michels) ; to change the magnetic susceptibility (K. Honda and Y. Shimizu) ; to distort the lattice structure (A. F. Joffé) ; to modify the sliding friction (R. B. Dow) ; to modify the contact potential (W. Ende) ; to modify the photo-electric current (R. F. Hanstock) ; to modify the triboelectric effect (R. F. Hanstock) ; etc.

F. Osmond pointed out that in the **crystal boundaries** between adjacent crystals, differently oriented, there must be many pockets so small that no crystal unit can fit into them.

When two grains possessing different orientation touch one another, their respective reticular systems cannot interlock, and there are strong reasons for the belief that there exists between the two grains a sort of amorphous envelope, the average thickness of which is of the same order as that of the crystalline molecule. If it be assumed, as it is admissible to do, that in the case of hardened steel the average diameter of the actual grain—invisible under the microscope—is also of the same order of size, the idea might be entertained that in hardened steel the iron might be amorphous.

G. D. Bengough suggested that the reason why rupture usually avoids the crystal boundaries is because these are stronger than the crystals themselves, since they are filled with an **intercrystalline cement** of amorphous metal. J. E. Sears also explained some of the anomalies in the elastic properties of metals by supposing them to consist of crystalline grains held together by an amorphous cement. The idea was developed by W. Rosenhain and D. Ewen. W. Rosenhain assumes that the intercrystalline cement is amorphous iron like G. T. Beilby's strong, hard, and brittle amorphous iron. The latter is produced by the severe straining of the crystalline metal, the former, by the solidification of liquid layers enclosed in such narrow spaces that they cannot assume a crystalline orientation. Some circumstantial evidence is quoted in support of the hypothesis : (i) the widening of the grain boundaries by etching ; (ii) the greater loss by volatilization when fine-grained metals are heated in vacuo than when coarse-grained metals are similarly treated ; (iii) the embrittling of silver by prolonged heating in vacuo is attributed to the loss of intercrystalline cohesion by the volatilization of the bond ; and (iv) the intergranular fracture which occurs when metals under stress are heated just below their m.p. It is assumed that the solution and vapour pressures of the amorphous material then are those of the crystalline metal. H. M. Howe considers this evidence extremely weak, because the facts quoted can be explained in other ways. W. Rosenhain and J. C. W. Humfrey observed (v) that as the temp. rises and the rate of straining decreases, rupture in ferrite tends to become intergranular rather than intercrystalline. The amorphous intercrystalline cement, behaving like ordinary undercooled solids, becomes a viscous liquid as the temp. is raised, and

thus offers less and less resistance, until it yields to the stress. The brittleness which accompanies coarseness of grain is explained by assuming that slip occurs simultaneously along the whole of any one plane, and this creates a weak mobile state along the whole of that plane; so that with coarse crystals, where the length and breadth of each plane is relatively large, the metal becomes relatively weak and rupture occurs. Thus, F. Osmond and co-workers found that a chisel-blow along one of the cubic cleavages of an isolated crystal of ferrite split it easily without deformation, whereas a similar blow at an angle of 45° to the cleavage plane cut the crystal without breaking it. F. C. Thompson developed a theory that the inter-crystalline strength will be greatest when the intercrystalline film is thinnest.

G. T. Beilby showed that amorphous iron is probably brittle and hard like other vitreous, amorphous substances—e.g. glass. R. J. Anderson and J. T. Norton failed to find X-ray evidence of an amorphous phase; they said that the polished surfaces of metals give a radiogram of the same pattern as severely cold-worked metals, and inferred that the surface layer consists of innumerable submicroscopic crystalline fragments, and not of amorphous metal, which should give black bands in the diffraction pattern. L. Cammen suggested that the crystals do not have an intermediate amorphous cement, but rather a matrix of extremely fine crystalline matter in which are embedded visible crystals, presumably of the same composition as the matrix. F. B. Foley also said that the growth of crystals in the freezing metal takes place atom by atom, and not cube by cube. This is taken to mean that no amorphous cement exists at the grain boundaries. The intercrystalline fracture at high temp. is due to a weakness of the structure of the boundaries, for the atoms at the boundaries are only loosely held, having become detached from the lattice of the crystal, and are consumed in the process of crystal growth, not having finally settled into the lattice of the growing crystals. When ferrite separates from austenite, the ferrite is not formed within the crystals and rejected at the boundaries; rather does the ferrite form at the boundaries of the austenite crystals. Atoms at the crystal boundaries are freer to assume new orientations; they possess energy in excess of that necessary for maintaining their positions in the lattice. The sub-ject was discussed by F. Hargreaves and R. J. Hills.

C. A. Edwards and H. C. H. Carpenter assumed that when steel is quenched, a pronounced twinning of the crystals occurs, and that the hard, amorphous, vitreous layers, formed on the gliding planes during the internal slipping or twinning, are retained by quick cooling. This hypothesis brings the hardening by cold-working and hardening by quenching into close relationship; both are due to the formation of amorphous layers by intercrystalline movement or slip, although the agencies producing the slipping are different. This is in agreement with F. Osmond's state-ment: If it be assumed, as is permissible, that in the case of hardened steel the average diameter of the actual grain, invisible under the microscope, is of the same size as the crystal molecule, the idea might be entertained that in hardened steel the iron might be amorphous. In order to agree with the observation that all carbon steels are magnetic, no matter how quickly they are quenched from a high temp., it is supposed that the amorphous layers—decrystallized γ-iron—are magnetic. According to W. E. Ruder, the intergranular cement in iron containing 4 per cent. silicon may be completely removed by making the alloy an anode in a soln. of potassium dichromate; or by heating the alloy in hydrogen at a temp. just below the m.p.

W. D. Bancroft objected to the amorphous film theory that its advocates have taken whatever properties they needed and have assigned them arbitrarily to the hypothetical amorphous phase. G. Tammann suggested that the amorphous film theory violates the phase rule—1. 9, 5—which shows that the liquid of a pure metal can exist in contact and in equilibrium with its own solid only at one definite temp.—press. constant. W. Rosenhain, however, showed that the deductions from the phase rule make no stipulation as to the time necessary for an unstable phase to pass into a stable phase. The phase rule gives no indication whether an indefinitely

large number of years or a movement is needed for the change. G. Tammann, and M. Hasselblatt also showed that since the crystalline state is more stable than the amorphous or undercooled liquid state, the amorphous phase should tend to become crystalline and not conversely. This objection does not allow for internal pressure. Again, the amorphous phase is bulkier than the crystalline phase, so that the effect of press. should convert the amorphous into the crystalline solid—*vide* 1. 9, 4—but only when the liquid phase is free to escape—*vide* 1. 13, 18. E. Heyn assumes that the contact films differ from the undeformed metal, but are not amorphous. The difference is due to surface tension. The total surface tension of the films with a fine-grained metal is greater than when the metal is coarse-grained ; as a result the small grains have a tendency to unite and become large ; while deformed grains have a tendency to become equiaxial, and, as observed in other cases by O. Lehmann, to combine into a single homogeneous crystal. The variation in surface energy is supposed to explain the changes in physical properties which are produced by plastic deformation ; but H. M. Howe said that it does not explain the phenomena attending slip—*vide supra*. The subject was discussed by J. H. Andrew.

G. Tammann inferred that the hardening, etc., during plastic deformation is due to the crystal grains being subdivided into an increasing number of polyhedra or lamellæ through the formation of gliding planes, and without any destruction of the true crystalline arrangement. The increase in the energy on deformation, observed by G. Tammann, and H. Schottky, is absorbed owing to the formation of so many new boundary surfaces, and this reappears in the hardened metal as an increased soln. press., etc. Hence, a worked metal differs from an unworked metal in having its crystals definitely oriented owing to the development of cleavage lamellæ and twinning. C. Chappell modified the hypothesis in some directions. He assumed that deformation does not in the first instance destroy the continuity of the molecules across the cleavage or gliding planes, but produces between them at those points a condition of high tension. By further deformation along one of these planes the tension becomes greater than molecular cohesion, the molecular continuity is broken, and the deformation along this plane becomes permanent. By the simple grinding together of these two surfaces, by further deformation, a layer of débris is produced between them, as would be the case if two stones were rubbed together. This layer of powdered ferrite retains its crystalline character, and can be regarded as being in a *metacrystalline state* likely to possess a very low crystallization temp. It is probable that the parallel markings observed in severely deformed ferrite crystals at 350° to 500° are the result of the recrystallization of this material and of the severely deformed adjacent parts. The decrease in density which accompanies plastic deformation is due to the crystalline débris along the cleavage planes occupying a greater vol. in its irregularly arranged condition than when fitted accurately together in the crystalline mass, just as an irregular heap of bricks occupies a greater volume than when the bricks are built into a wall. C. Chappell's metacrystalline state recalls W. Guertler's assumption that the intercrystalline matter is in a *paracrystalline state*, or *weniger stabil orientiert*. According to J. C. W. Humfrey, the slow contraction of tensile test-pieces on releasing the stress after plastic deformation and the decreased elastic limit in compression after plastic tensile-strain are due to the elastic skin enclosing the crystals. According to C. Chappell, the slow contraction after plastic tensile strain is simply due to the condition of high molecular tension existing on the planes of slip, in consequence of which the crystals seek to return to their previous shape, like springs in tension. Rise of temp., by decreasing the frictional resistance of the material, accelerates this contraction. The restoration of elastic properties by heating at very low temp., as also the disappearance of slip-bands on heating, may be attributed to this same effect, whereby rise of temp. facilitates the release of the condition of internal molecular tension, thus restoring normal conditions within the crystals. It is also evident that the molecular tension produced on the cleavage planes by plastic

tensile strain will assist a force subsequently applied in the opposite direction, thus aiding compression after previously applied tension.

There are other hypotheses as to the nature of the intercrystalline boundaries, which experiment has shown to be the seat of cohesive forces so powerful that fracture, as a rule, runs across the grains themselves rather than follow the intercrystalline boundaries—*vide infra*, tensile strength. F. Hargreaves and R. J. Hills postulated the existence of a transition zone between two orientations, so that the intercrystalline phase is not amorphous material, because for the same two orientations and the same relative position of the boundary, the same pattern of atomic arrangement is always found on the unstressed metal. J. O. Arnold referred to the interlocking of the crystals across their boundaries, presumably due to the dendritic interlacing of adjoining crystals. W. Rosenhain also suggested that the strength of intercrystalline cohesion is partly due to the interlocking of the skeleton arms which the crystals develop during their first formation. Owing to the dendritic branching of the crystals at the boundaries, the boundaries may be more or less jagged or saw-toothed. The intercrystalline boundaries are thus considered to be regions of mixed orientation, which offer greater resistance to slip than regions of uniform orientation. Some branches of the dendrites follow the orientation of a grain on the right and others the orientation of the grain on the left of the boundary. The intercrystalline boundaries form a network of cells upon which the true resistance of the metal depends. Plastic deformation occurs when the cell-walls begin to give way and in doing so they carry with them the less resisting masses of the crystalline grains. This agrees with the observed relations between the slip-bands and the intercrystalline boundaries. F. Osmond and co-workers also observed the frequent doubling of the intercrystalline boundaries of the crystal grains of ferrite in purified iron.

W. Barlow suggested that surrounding each growing crystal there is a layer of molecules which, although not held together in the rigid solid condition, yet are tending to a regular formation such as exists within the crystal itself. According to J. C. W. Humfrey, when two crystals are gradually growing towards one another, each will endeavour to marshal the surrounding molecules of the liquid to its own orientation. If equilibrium could be established before the temp. fell below that at which crystallization becomes difficult, there would be formed between two crystals a layer of matter in which the molecules are so arranged as to pass by small displacements from the orientation of one crystal to that of the other. If the cooling be rapid enough, before the state of equilibrium can be attained the layer of liquid between two crystals would become so viscous as to remain in the amorphous, undercooled state. In such a case the amorphous layer would be connected to each crystal by molecules whose distribution gradually approached that of the crystal nearest them. Subsequent annealing would tend to reduce the layer of undercooled liquid and bring about the gradual and continuous change representing complete equilibrium. When the system is in equilibrium, in any particular plane of the region between two crystals in which displacement from the orientation of either occurs, the thickness will depend on the relative difference of orientations in this plane. The greater the difference of orientation, the more adjustment is required and the greater thickness necessary to complete it. No displacement of either orientation will be required in passing from one crystal to an adjacent crystal similarly oriented; and if this plane be also one of gliding or cleavage, these properties should be continuous between two crystals. This is in agreement with the microscopic study of strain phenomena. J. C. W. Humfrey offered as evidence of the existence of some such boundary the curvature and forking of slip-bands in ferrite as they approach the boundaries. This curvature, however, was regarded by H. M. Howe as facilitating the propagation of slip along the slip-planes of the grain on the other side of the boundaries.

H. M. Howe was unable to confirm the existence of a region of mixed orientation. He considered that surface tension opposes the crystallizing force, thus tending

to straighten and smooth the grain boundaries and efface the initial dendritic inter-locking. It is also difficult to suppose that such a state of things at the boundaries of the grains can survive the obliteration and regeneration of grain boundaries which must occur during the various transformations which steel undergoes during the mechanical kneading which attends rolling, forging, wire-drawing, and annealing. Grain-growth would also tend to efface the interlocking or mixed orientation assumed to exist between adjoining crystals. H. M. Howe does not consider that the theories of interlocking and of mixed orientation explain adequately how defor-mation and rupture avoid the grain boundaries and preferentially cross the grains themselves. Nor does he consider that the amorphous cement filling can explain this, because an intergranular layer at once discontinuous and approximately of molecular thickness is not likely to offer sufficient resistance to a shearing stress. He prefers to modify the amorphous film theory by assuming that there is a pro-gressive accumulation of amorphous metal about the crystal boundaries owing to the breaking up of crystalline metal caused by the discontinuity of the slip-planes in adjoining crystal grains. The generation of the amorphous metal in the dis-turbed region would add to the discontinuity in opposing the propagation of slip past the grain boundaries. Once such a layer is formed along the grain boundaries, any further slip has to overcome (i) the resistance which this amorphous material opposes to slip because of the absence of slip-planes, planes of low cohesion ; and (ii) any increase in the strength of the grain boundary regions.

The **grain-size of the crystals** of metals is affected by the rate of cooling during solidification, so that a large casting will have an average grain-size different from that of a small casting cast at the same temp., because of the different rates of cooling. As a rule, with slow solidification, crystallization proceeds from a relatively small number of nuclei, and the final grain-size will be relatively large ; on the other hand, with rapid solidification, crystallization proceeds from a relatively large number of centres, and the final grain-size is relatively small. If metals be exposed to a high enough temp., there is a tendency for the crystal grains to enlarge, but it is doubtful if the grain-growth will take place below the m.p. unless the metal has been previously strained, or unless, as in the case of iron, allotropic transformations occur. When the deformed metals are heated—annealed—a rearrangement of the crystals—a **recrystallization** or **grain-growth**—occurs, tending to remove the strain of distortion produced by cold-working and to produce equiaxial grains. G. Tam-mann and W. Crone observed that quenched electrolytic iron had 3·4 crystals per sq. mm., and slowly cooled iron, 1·8 crystals per sq. mm.—the numbers of crystals after recrystallization at 880° were respectively 163·6 and 107·7 per sq. mm. Z. Jeffries and R. S. Archer [8] gave 450° for the temp. of recrystallization ; and the theory of the subject was discussed by J. A. M. van Liempt. H. Altreter supposed that grain-growth and recrystallization are the result of thermodynamic instability, and that the energy changes which accompany cold-working are partly reversible and partly irreversible. According to Z. Jeffries and R. S. Archer, grain-growth in solids can occur with (i) worked metals, (ii) compressed powders, (iii) electro-deposited metals, (iv) when a metal changes its allotropic form, and (v) when a new phase is formed in the solid state. According to A. Sauveur, the dimensions of the grains so produced will be dependent on (i) the nature of the metal, (ii) the amount of deformation or mechanical work, (iii) the size of the distorted grains, (iv) the temp. of deformation, (v) the annealing temp., (vi) the duration of the annealing, and (vii) the rate of cooling from the initial temp.

H. M. Howe called the temp. at which the recrystallization or grain-growth begins the *germinative temperature* ; the range of temp. below the germinative temp., the *inert range* ; and the range of temp. above the germinating temp., the *growth range*. According to Z. Jeffries and R. S. Archer, certain conditions of non-uniformity—grain-size contrast, strain gradients, concentration gradients, and obstruction gradients—may result in the formation of abnormally large grains. The presence of foreign matter or of a second phase introduces mechanical obstruction to grain-growth ; and resistance increases as the pro-portion of foreign matter or other phase increases, and as the grain-size diminishes.

The presence of a certain amount of obstructive matter may promote germination. The higher the germinative temp., the coarser the grain-size and the quicker the growth. The more rapid the rise of temp. through the germinative temp. range, within certain limits, the finer the grain-size.

Z. Jeffries and R. S. Archer showed that the grain-size in any given metal after complete recrystallization is normally smaller the lower the recrystallization temp. Above this temp. the grain-size is normally greater the higher the temp. and the longer the exposure. The higher the temp., the more rapid the grain-growth. At a temp. near the m.p. a few seconds may suffice to produce grains which do not change on a prolonged exposure. They said :

The grain-size in cast metals is usually small in proportion to the rate of solidification. In such metals as undergo no phase change in the solid state grain-size cannot be appreciably
FIG. 164.— The Effect of Time on the Grain-size.
FIG. 165.—The Effect of Temperature on the Grain-size.

changed by heating below the melting point. Grain-growth in the solid state may occur under various conditions, as when iron changes its allotropic form, and in alloys when a new phase is formed in the solid state. Deformation, smallness of grain, purity, low temp. deformation, and long heating lower recrystallization temp. Grain-size after complete recrystallization is normally smaller the lower the recrystallization temp. High temp. increases grain-size. The higher the temp. the more rapid the grain-growth. The formation of abnormally large grains (germination) is sometimes due to non-uniform conditions. Such conditions are grain-size contrast and strain, temp., concentration. and obstruction " gradients." Presence of foreign matter or of a second phase introduces mechanical obstruction to grain-growth. A certain amount of obstruction promotes germination. The higher the germinative temp., the larger grains and the more rapid their growth. The more rapid the heating through the germinative temp. range (within limits), the finer the grain-size.
FIG. 166.—Grain-growth in Armco Iron.
FIG. 167.—The Effect of Carbon on the Grain-size.
FIG. 168.—The Effect of Manganese on the Grain-size.

P. Oberhoffer's curves for the effect of time on the grain-size of ferrite are shown in Fig. 164 ; and his curve for the effect of temp. on the grain-size of cast steel with 0·27 per cent. of carbon, in Fig. 165. Observations on this subject were also made by L. E. Benson and F. C. Thompson, some of whose results are indicated in Figs. 166, 167, and 168. The ordinates in all cases represent the number of grains per sq. mm., so that the greater the number the smaller the grain-size. Fig. 166 shows. the effect with armco iron ; the results with pearlite

are similar. Fig. 167 shows the influence of carbon on the grain-size after annealing for an hour; and Fig. 168, the effect of manganese on the grain-size after annealing for an hour. R. Johnson found that the temp. at which recrystallization begins and ends are higher the higher the proportion of carbon. Observations on grain-growth were made by C. Agte and K. Becker, R. J. Anderson, A. E. van Arkel and co-workers, J. O. Arnold, E. J. Ball, P. Beck and M. Polanyi, A. A. Blue, A. A. Botschwar, H. Brandes, J. A. Brinell, E. R. Brophy and R. H. Harrington, Y. Chu-Phay, W. J. Crook, J. Czochralsky, K. Daeves, F. S. Dodd, C. A. Edwards and L. B. Pfeil, H. Fay and S. Badlam, P. Fischer, W. Fraenkel, J. R. Freeman, H. Giersberg, L. Grenet, D. Hanson, W. Heike and F. Westerholt, E. Heyn, V. E. Hillman and F. L. Coonan, O. F. Hudson, H. von Jüptner, F. Körber, V. N. Krivobok, R. Kühnel, J. A. M. van Liempt, H. Lüpfert, C. H. Mathewson and A. Philips, R. G. Morse, C. H. Risdale, F. Sauerwald, A. Sauveur, E. Scheil, W. Schneider and E. Houdremont, H. Schottky and H. Jungbluth, M. von Schwarz, W. Tafel and co-workers, G. Tammann and W. Salze, D. Tschernoff, G. W. Walker, H. C. Wang, etc. In a general way, with eutectoidal steels which have been previously deformed or strained, the higher the temp. above the Ac₁-arrest from
FIGS. 169, 170, and 171.—The Grain-size acquired at 966°, 1212°, and 1339° (W. Campbell).

which the steel cools, the larger the size of the crystal grains ; while if the Ac₁-arrest is the highest temp. attained, then the steel will have the finest grain structure it can assume. H. M. Howe and A. Sauveur, indeed, found empirically for one sample that if θ denotes the highest temp. in the annealing furnace, and A the average area of the grain in sq. mm., $\theta = 680 + 281250A$. The results of W. Campbell's observations on the grain-size at 966°, 1212°, and 1339° are illustrated by Figs. 169 to 171 ($\times 33$). If hardened or unhardened eutectoidal or hypereutectoidal steels be heated above the Ac₁-arrest, all previous crystalline structure is obliterated and replaced by the finest possible structure the metal can assume at the given temp. The breaking up and obliteration of the old structure may not be complete with some hypoeutectoidal steels. According to K. Daeves, iron containing a small proportion of carbon acquires a new structure when heated to 1125°, owing to the separation of ferrite and pearlite in certain directions which are oriented crystallographically. J. E. Stead studied the recrystallization of mechanically deformed iron and steel, and found :

In practically carbonless iron, and steels of fine grain produced by forging, the grains increase slowly in size at 500°, and more rapidly between 600° and 750° ; and it is possible by heating for a few hours at about 700° to develop granular masses of exceeding coarseness. When iron is made coarsely granular, by long heating at a dull red-heat, and heated between 750° and 870°, the structure is as a rule not altered to any material extent, but as soon

as the temp. rises to about 900°, the granules again become small. . . . Elongated crystals of ferrite, produced by severe cold deformation, usually split up on recrystallization into smaller crystals whose diameter in each direction corresponds approximately with the breadth of the original elongated ones.

H. C. H. Carpenter and C. F. Elam concluded that in the recrystallization of metals : (i) growth may take place either by a large crystal growing into a smaller one or conversely, *i.e.* growth is independent of the size of crystals—*vide* 1. 10, 1 ; (ii) the relative orientation of the crystal being grown into and that which is growing does not affect the growth ; (iii) a crystal being invaded by one crystal may at the same time grow at the expense of another ; (iv) the rate of growth is not constant for a given time at any particular temp. ; and (v) the change of orientation is accompanied by a difference of level of the surface, which is the boundary marking observed.

A. Pomp and S. Weichert noticed that the recrystallization of cold-rolled, low-carbon steel was first noticeable at 600°. The results of J. E. Stead on hypo-eutectoidal steel are represented graphically in Fig. 172, along with H. M. Howe's observations on a eutectoidal steel. The dotted continuation of A indicates that the grains of austenite above Ac_1 begin increasing in size from the time they begin to form as soon as the temp. rises above Ac_1. In both steels refining occurs on passing the Ac_1-arrest, but with low-carbon steel there is a coarsening and consequent embrittling as the temp. approaches the Ac_1-arrest. The brittleness caused by over-heating high-carbon steel, and that due to the long exposure of
FIG. 172.—The Effect of Temperature on the Grain-size of Steel.
FIG. 173.—The Effect of Temperature on the Grain-size of Iron.

low-carbon steel between 500° and 700°, are both cured and the metal refined by heating it beyond the Ac_1-arrest. As the temp. approaches the Ac_3-arrest, the free ferrite becomes progressively less owing to its absorption by the austenite, but its position does not appear to change, for its grain-size does not alter. On passing the Ac_3-arrest, however, the absorption of the ferrite is completed, and the coarse granulation and brittleness also disappear. The different behaviour of the two steels as the temp. approaches 700° is connected with their constitution. The high-carbon steel consists of a ground mass of pearlite penetrated by a thin network of ferrite, whereas with the low-carbon steel the pearlite is present in scattered masses in an excess of ferrite. Hence, the coarsening of the grain of the low-carbon steel as the temp. approaches 700° is due to a coarsening of ferrite rather than to a change in the pearlite. The observations of C. Chappell on the recrystallization of Swedish wrought iron and mild steel at different temp. are summarized in Fig. 173. The average grain-sizes of the two materials are similar at about 650°, but at 850° the crystal grains of wrought iron have six times the average diameter of those of the mild steel.

H. Lüpfert studied the effect of time, annealing temperature, and speed of cooling on the grain-size of steel with 0·196 per cent. of carbon, and the results are summarized in Figs. 174 and 175. Similarly with the results on chrome-nickel steel, containing 4·0 per cent. nickel, 0·7 per cent. chromium, and 0·1 per cent. carbon, which are summarized in Figs. 176 and 177. B. Jonsen found that with steels containing 0·60 to 1·15 per cent. of carbon, the temp. at which crystallization begins and ends are the higher the higher is the proportion of carbon. The optimum temp.

lies between 650° and the Ac₁-point. W. Crone, and F. Wever and N. Engel also studied the effect of the rate of cooling on the structure of the carbon-iron alloys.

According to P. Goerens, the ferrite in cold-drawn iron and steel recrystallizes at temp. between 520° and 580° ; the elongated ferrite crystals are then replaced by ordinary polyhedral or allotrimorphic shapes.   H. O'Neil found that recrystallization commences at the grain boundaries and at etch bands where the metal is
FIG. 174.—The Effect of Annealing Temperature and Time on the Grain-size of Steel cooled in the Kiln.
FIG. 175.—The Effect of Annealing Temperature and Time on the Grain-size of Steel cooled in Air.

hardest. H. le Chatelier, and G. Charpy showed that in the annealing of a metal which had suffered a local deformation, abnormally large crystals developed, but only in the deformed area. A. Sauveur also observed that this remarkable growth of crystals takes place only when the iron has been subjected to an intermediate degree of deformation, such that when stressed beyond this critical range no growth takes place on annealing at 650°. F. Robin found that in very soft steel which had been
FIG. 176.—The Effect of Annealing Temperature and Time on the Grain-size of Chrome-Nickel Steel cooled in Kiln.
FIG. 177.—The Effect of Annealing Temperature and Time on the Grain-size of Chrome-Nickel Steel cooled in Air.

deformed in the cold the crystal size reaches a maximum between 700° and 750°, and decreases slightly with a rise of temp. to 900°, where the gross crystallization is destroyed.

Observations on the recrystallization of cold-worked and other forms of iron and other metals were also made by R. P. Ahrell, H. Allen, A. E. van Arkel, J. Bauschinger, P. Beck, R. Becker, J. D. Brunton, G. Charpy, E. O. Courtman, K. Daeves, U. Dehlinger, A. N. Dovrovidoff and Y. V. Grdina, O. W. Ellis,

J. R. Freeman, O. Fuchs, N. P. Goss, L. Grenet, H. Hanemann, H. Hanemann and C. Lind, E. Heyn, E. Heyn and O. Bauer, H. M. Howe, A. Joisten, T. von Karman, O. von Keil, G. L. Kelley, F. Körber, P. Longmuir, H. Lüpfert, D. J. McAdam, G. Masing, E. Maurer, K. Neu, P. Oberhoffer and co-workers, A. Pomp, A. M. Portevin, E. Preuss, H. E. Publow and co-workers, H. Puppe, E. Rasch, O. Reinhold, F. Riedel, W. Rosenhain, M. Rudeloff, W. E. Ruder, K. Rummel, A. Sauveur, H. M. Howe and A. Sauveur, E. Scheil, E. H. Schulz and J. Göbel, W. Schwinning and E. Strobel, K. A. Seyrich, R. H. Sherry, C. Sobbe, A. Stadler, C. Sutor, W. Tafel, G. Tammann, R. Vogel, M. Volmer, H. Wald, J. H. Whiteley, M. H. Wickhorst, and F. Wüst and W. C. Huntington.

The general results show that the grain-size developed on recrystallization is dependent on the amount or degree of mechanical deformation. P. Oberhoffer and W. Oertel represented the effect of mechanical work and temp. on the grain-size of electrolytic iron, in terms of an average crystal, by Fig. 178, a diagram analogous to that employed for the case of tin—7. 46, 4. The results show that the temp. at which recrystallization begins depends on the amount of previous deformation, being lower as the amount is increased; if the deformation is severe, the grain-growth is slow up to 700°, and above that it is rapid; and if the amount of deformation is slight, the growth is rapid even below the critical range. H. Hanemann and co-workers observed that the curve showing the relation between the grain-size and degree of deformation and that showing the relation between the deformation and the temp. of recrystallization are hyperbolic. The parameter of the hyperbola for the grain-size of steel is a linear function of the crystallization temp. If θ is the minimum temp. at which crystallization occurs; v, the degree of deformation; ϕ, the grain-size; and θ, the temp. of recrystallization, then $2v\phi^2=a^2(\theta-\theta_r)$, where a is a constant, and $\theta_r=620°$. The subject was discussed by P. Oberhoffer and W. Oertel, and W. Riede—*vide infra*, alternating stress tests. The subject was also studied by H. E. Publow and S. E. Sinclair, and M. von Moos, P. Oberhoffer and W. Oertel. According to F. C. Kelley, rapid grain-growth results from diffusion, when the direction of the grains is parallel to that of the diffusion. G. Tammann said :

FIG. 178.—The Effect of Temperature and Mechanical Work on the Grain-size of Electrolytic Iron.

Two contiguous crystals can be in equilibrium with one another only when the crystallographic equilibrium lattice planes of both crystals lie together in the same plane at the surface of contact, that is, when the space-lattices of both crystals form a single lattice, or when the plane of contact is a twinning plane. If one or the other of these conditions is not fulfilled, then when the temp. is raised sufficiently to allow of a certain amount of change in the position of the atoms or molecules in the lattice, new lattices of mean orientation to the surface of contact will be formed, that is, a recrystallization will take place.

Abnormal crystallization does not occur if the deformation be above or below; there is a maximum and minimum limit of straining required to develop the abnormal crystals. C. Chappell demonstrated this by heating a broken test-bar of wrought iron to 870°. The crystals were found to be normal at both ends and very large in the middle. He also found that when iron of a high degree of purity is strained, large crystals are always produced, provided the temp. at which the material is deformed is not above 900°. C. Chappell also showed that in suitably deformed iron crystal growth between 850° and 870° is extremely rapid. The less the strain, the higher the annealing temp. necessary to obtain very large crystals, and the larger these crystals will be, provided a certain minimum strain be exceeded. The correct degree of plastic deformation applied at any temp. up to 900° will cause the production of abnormally large crystals on annealing. The presence of carbon reduces

the size of the largest crystals and makes a greater strain necessary to induce their growth. When carbon is present, as in the mild steels, the abnormal growth is prevented by the solid soln. of carbide in iron, which separates the various crystals from one another—*vide supra*, germinative temp. C. Chappell gave two explanations of the rôle of plastic deformation in promoting the union of the ferrite crystals : (i) If identity of orientation is the only condition necessary for the union of adjacent crystals, plastic deformation may be supposed to act by increasing the potential energy of the crystals, enabling them to bring about this rotation of their axes parallel to each other with greater ease and rapidity when the temp. is raised. (ii) The union of ferrite crystals may be considered to be analogous with the welding of two pieces of iron in which work is necessary to break up any separating layer of oxide or flux and establish molecular contact. An intercrystalline cement, acting as a separating layer, is penetrated by plastic deformation, and two crystals are brought in contact so that on reaching a high enough temp. they weld together directly.

Z. Jeffries studied what he called the effect of inheritance on the grain-size of iron and of carbon steels, and the results were summarized as follows :

(i) The ferrite grain-size in pure iron, the ferrite and pearlite grain-size in hypoeutectoid steel, the pearlite grain-size in eutectoid steel, and the cementite and pearlite grain-size of hypereutectoid steel are not inherited from the grain-size of the mother-austenite. (ii) The only structural feature that is generally inherited from the austenite of hypo- and hypereutectoid steels, on cooling through their transformation ranges, is the position of the excess ferrite or cementite at the austenite grain boundaries, sometimes causing complete and sometimes incomplete networks, which outline the old austenite grain boundaries. Rapid cooling through the transformation range will prevent the inheritance of this structural (network) feature. (iii) The austenite grain boundaries themselves are nearly always effaced in all steels and also in pure iron during the Ar_1-transformations. (iv) The grain-size refining of steel and iron is brought about by the combined effects of non-inheritance of the transformation products on either heating or cooling, *i.e.* the austenite transformation products do not inherit their grain-size from the austenite on cooling through the transformation range, nor does austenite inherit its grain-size from the structure which forms austenite on heating. (v) In general, both in iron and in carbon steels, the larger the austenite grain-size, the larger will be the grain-size of the transformation products on cooling. This, of course, assumes all other conditions constant except the austenite grain-size. Iron of a high degree of purity, such as electrolytic iron, is an exception to this general rule. In this instance small austenite grains may form very large ferrite grains on cooling throughout the Ar_3-arrest. (vi) In iron and steel, the larger the ferrite, cementite, or pearlite grain-size, the larger will be the austenite grain-size on heating above the Ac-transformations. (vii) The faster the rate of cooling of iron and steel through the Ar_1-transformation range, the smaller will be the grain-size of the transformation products. (viii) The faster the rate of heating of iron and steel, other conditions remaining the same, the smaller will be the austenite grain-size. (ix) The greater the temp. gradient during the transformations in iron and steel on heating or cooling, the larger will be the grain-size. (x) If the grain-size of a transformation product in iron and steel immediately after the transformation is smaller than the equilibrium grain-size of that product under the existing conditions, the equilibrium grain-size will be established in accordance with the known laws of grain-growth. (xi) A single grain of any constituent in iron or steel (austenite, ferrite, pearlite), when caused by thermal treatment to undergo one of the polymorphic transformations, must transform from at least one nucleus, but may, and nearly always does, transform from more than one nucleus.

C. A. Edwards and L. B. Pfeil studied the conditions under which large crystals can be obtained. They found that a grain-size approximately 120 grains per sq. mm. can be obtained by decarburizing iron by heating at 950° for 48 hrs., followed by slow cooling—12 hrs. from 950° to 100°. The carbon can be all removed if hydrogen is passed through the furnace while the metal is being heated. They also found that the orientation of the large crystals seems to bear a relation to the direction of straining and to the surface of the strips. The critical strain required to produce very large crystal growth on subsequent annealing varies with the initial size of the grain. A greater strain is needed as the grain-size increases. With very large crystals sufficient strain cannot be applied, owing to the recrystallization at the boundaries of the crystal. Surface crystals of the original finely crystalline aggregate behave differently from the interior ones, for they require a greater tensile

strain before they disappear. The subject was discussed by E. Sutter. C. A. Edwards and L. B. Pfeil found that the deformation of single crystals occurs by a process of slip causing little change in the crystal lattice. They added :

If, however, two crystals in contact are deformed, interference with slip will occur, owing to the change in the direction of the slip-planes in passing from one crystal to another. Under these circumstances some other kind of movement occurs during deformation ; this second kind of movement will be most intense at and near the crystal boundaries, and less so as the distance from the boundaries increases. X-ray analysis does not indicate any difference between the lattice constants of cold-worked and of annealed metals, but shows a relation in the former between the directions of the crystallographic axes and the direction of straining. The second type of deformation (caused by interference with slip) is inter-preted, therefore, as a rotation of the crystallographic axes accompanied by elastic strains (the latter not being detected by X-ray analysis). The depth to which this change pene-trates from the boundaries depends upon the degree of deformation. With small crystals but little deformation will cause the depth to correspond with the radius of the crystals. The larger the crystals, the greater will be the deformation necessary to cause the change to reach the centres of the crystals. When this second type of deformation has penetrated to the crystal centres (and the strain at the crystal boundaries has not exceeded a certain value), and the degree of axial alignment due to rotation has proceeded to such an extent that, on annealing, it is more easy for the atoms to form a single crystal than to revert to their original orientations. With very large crystals, however, before the second type of deformation has penetrated to the centres, the strain set up at and near the crystal boundaries has become so great that, on annealing, it is more easy for the atoms in these highly strained regions to form new crystals (*i.e.* recrystallization) than for a process of perfectly uniform and stable alignment to occur. For equal amounts of tensile deformation, a surface crystal, not being subjected to interference with slip on all sides, is not affected to the same degree as an interior crystal, so far as the second type of movement is concerned. A greater degree of deformation is in consequence required before the change in surface crystals will be sufficiently complete to permit of growth or absorption during annealing. When, however, the critical degree of strain is caused by rolling, and the freedom of the surface crystals is thus at least partly removed, growth or absorption of the surface crystals can occur.

The Report of the Iron and Steel Institute on the nomenclature of metallo-graphy [9] defined **burnt steel** as follows :

The term " burnt " is applied to metal which is brittle in consequence of an alteration in its mass caused by excessive heating. A so-called burnt steel is not necessarily oxidized in its mass. Near to the external surface, if carbon is low or absent, intergranular layers of oxide of iron may sometimes be detected. The chemical composition is not necessarily altered by the so-called burning. Steel may, on heating to a very high temp. in an inert atmosphere, develop, after cooling, many of the properties of burnt steel. Burnt steel is generally coarsely granular and is easily fractured.

It also said that **overheated steel** is a term applied to steel that has been heated to excess, but not burnt. Oxidized membranes are often found surrounding some of the grains of burnt steel, and in that case the original state cannot be restored by forging, since the films of oxide would prevent the welding of adjacent grains. H. M. Howe said that steel known as overheated has a coarse structure which may be removed more or less completely by reheating or careful forging. If the over-heating has been extreme, the cohesion between the adjacent grains becomes so feeble that they are forced apart to a certain extent by gas evolved from within. Part at least of this gas is carbon monoxide formed by the union of infiltering atm. oxygen with the carbon of the steel, although other gases, like hydrogen and nitrogen, may also contribute, as they are thrown out of soln. by a rise of temp. Burnt steel is red-short as well as cold-short, and brittle ; it can be forged and welded only with care ; it has a low tensile strength ; and its fracture is coarse and even flaky, crystalline, with brilliant facets. Excessively long or strong overheating produces burnt steel ; and the coarseness and brittleness due to burning are removed with greater difficulty and much less completely than those due to overheating. J. E. Stead said overheating occurs when the steel is heated at any point below that which produces incipient disintegration, and results in the formation of large crystals ; and burning occurs when the steel is heated at or above the point at which the disintegration occurs. Burnt steel is nearly always coarsely crystalline.

J. E. Stead added that the coarse crystalline structure of overheated steel, with 0·20 to 0·50 per cent. of carbon, exhibits triangular arrangements of ferrite and pearlite ; and that of steel with 0·50 to 0·70 per cent. of carbon exhibits large ferrite cell-walls with offshoots of ferrite penetrating the pearlite. A. S. Stansfield regarded the overheated steel as a steel that has been heated to the point of incipient fusion. J. E. Stead described this theory, and rejected the oxidizing gas hypothesis. In other words, it is assumed that the steel has been heated to a temp. between the liquidus and solidus curves, *i.e.* between AC and AE, Fig. 83. If this is the only reason, it follows that carbonless iron cannot be burnt, and that the higher the proportion of carbon, the greater the danger of burning. Thus, with a steel with 0·50 per cent. of carbon, the burning zone extends from about 1400° to 1450° ; with 1·0 per cent. carbon it extends from 1310° to 1410° ; and with 1·50 per cent. carbon, from 1210° to 1360°. The carbon increases the tendency to burning by lowering the m.p. and by widening the solidification zone, which is also the burning zone. An overheated steel has been heated close to but below the solidus curve, Fig. 83. A. W. Richards and J. E. Stead added that when steel is burnt by heating to incipient fusion, fusible globules or envelopes, rich in phosphorus, are formed round the crystals, and their presence or absence is regarded as a proof whether or not the steel has been burnt. If these globular specks rich in phosphorus are absent, it may be concluded that a red-short steel has not been burnt, but is naturally red-short. J. H. Andrew said that the over-heating of a mild steel occurs only when the temp. is sufficiently high to bring about a dissociation and diffusion of the carbide which, until this temp. is attained, forms as a conc. phase around the ferrite grains. The subject was also discussed by L. Aisenstein and co-workers, P. Bardenheuer and K. L. Zeyen, W. Campbell, W. H. Cathcart, K. F. Göransson, E. Heyn, H. M. Howe, W. E. Jominy, J. V. McCrae and co-workers, E. Pohl and co-workers, W. Rosenhain, J. E. Stead, L. W. Wild, and K. W. Zimmerschied, as well as in numerous books on the heat treatment of steels. H. Hanemann discussed the theory of over-heating grey cast iron.
